Introduction

Good air quality is vital to human health and the environment. Ozone and fine particulate matter ($PM_{2.5}$) are air pollutants with widespread health and environmental effects that derive from emissions from a variety of natural and human-caused sources, including industry, power plants, vehicles, and agriculture. Ozone is a colorless gas that forms in the atmosphere from emissions of other compounds. At ground level, ozone is a powerful oxidant that, when inhaled, affects the respiratory and cardiovascular system, causing a wide range of health outcomes including lung damage and premature mortality.[1,2] It also damages crops and natural vegetation.[1,3] $PM_{2.5}$ is defined as airborne particles with a diameter of 2.5 micrometers and smaller—about 30 times smaller than the width of a human hair. These small particles can be inhaled into the lungs, leading to health problems including cardiovascular disease, adverse birth outcomes, neurological disease, and increased risk of death.[4,5,6,7,8,9,10] $PM_{2.5}$ is a complex mixture of solid and liquid substances,[11] including particles emitted directly from combustion and those formed in the atmosphere from gases emitted from natural and human sources. $PM_{2.5}$ also contributes to regional haze, which can impair enjoyment of scenic vistas, including in national parks.

Ground-level ozone and $PM_{2.5}$ have declined in the US due to programs that lowered emissions. From 2000 to 2020, extreme ozone levels (98th percentile) declined by 18%,[12] and annual average $PM_{2.5}$ concentrations declined by 41%.[13] Continued reductions in human-caused emissions are projected to bring still cleaner air in the US.[14,15]

Despite these improvements, in 2021 nearly 102 million people lived in areas where pollution levels exceeded health-based air quality standards.[13] Estimates of annual US deaths from exposure to ambient ozone and $PM_{2.5}$ range from about 60,000[16]—more deaths than from either motor vehicle accidents, kidney disease, breast cancer, or prostate cancer—to 260,000[17,18,19] or more,[20] valued at $750 billion to $3 trillion (in 2022 dollars).[21,22] Air pollution damages to US crops are estimated at approximately $12 billion annually (in 2022 dollars).[23] The negative impacts of air pollution are not distributed equally, with communities of color and low-income communities disproportionately burdened.[24,25]

Climate change, driven mainly by human greenhouse gas (GHG) emissions that are not harmful to breathe at typical atmospheric levels, affects air pollutant concentrations through multiple pathways (KM 14.1) including wildfire smoke (KM 14.2) and affects aeroallergens (KM 14.4), with effects on health. Air pollutants also affect climate (KM 3.1), and the main sources of air pollutants are also the main sources of GHG emissions, suggesting that there is opportunity to address climate and air quality goals simultaneously (KM 14.5). Current inequities in air pollution exposure may be alleviated or worsened by the impacts of climate change and actions to reduce GHG emissions (KM 14.3).

Key Message 14.1

Climate Change Will Hamper Efforts to Improve US Air Quality

Climate change is projected to worsen air quality in many US regions (*medium confidence*), thereby harming human health and increasing premature death (*very likely*, *high confidence*). Extreme heat events, which can lead to high concentrations of air pollution, are projected to increase in severity and frequency (*very likely*, *very high confidence*), and the risk of exposure to airborne dust and wildfire smoke will increase with warmer and drier conditions in some regions (*very likely*, *high confidence*). Reducing air pollution concentrations will unequivocally help protect human health in a changing climate.

Air pollution concentrations are determined by natural and human-caused emissions and by atmospheric conditions, including temperature, humidity, and winds. Climate change is projected to worsen air quality in many regions, harming human health. Some of the largest increases in $PM_{2.5}$ and ozone exposure are expected in heat- and drought-prone regions (Figure 14.1) and in areas where vulnerable populations live (KM 14.3). For example, increasing heat and drought already contribute to more frequent wildfires and associated smoke episodes (KMs 14.2, 7.1). Severe climate change, with a US average warming of 9°–14°F, would increase annual US air pollution–related deaths by about 25,000 in 2100, relative to 2000.[26,27] This estimate assumes population growth but no change in emissions, including wildfire smoke. Given that wildfires and smoke $PM_{2.5}$ are projected to increase in a warmer climate (KM 14.2), this mortality rate may be an underestimate.

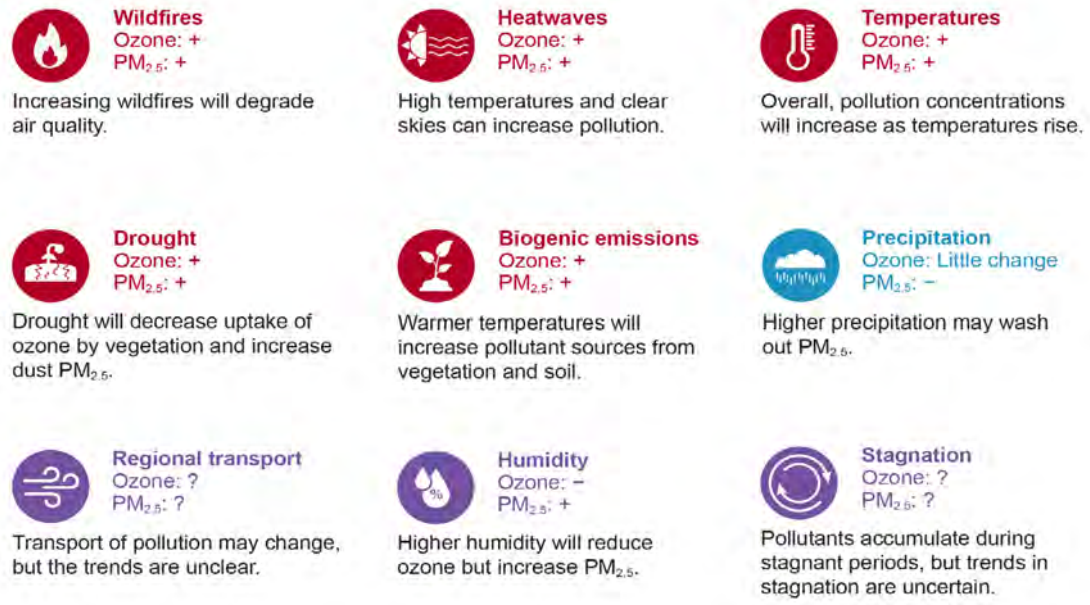
Climate change is expected to alter meteorology over the US in several ways that will directly degrade air quality (Figure 14.1). For example, ozone levels are higher on warm, sunny days because the chemical reactions that produce ozone speed up with temperature and sunlight. Exposure to these short-term ozone episodes has been linked to increased mortality.[28] Some gases that produce ozone and $PM_{2.5}$ come from soils and vegetation, and these emissions are sensitive to temperature and rainfall. Such processes typically lead to higher pollution levels during heatwaves, when exposure to $PM_{2.5}$ appears to be especially harmful.[29,30,31,32]

Local air pollution events are also strongly tied to large-scale weather patterns.[33,34,35,36] For example, cold fronts sweep clean air across the eastern US, clearing the air of pollution.[37] How climate change will affect these large-scale patterns is not well known. In the eastern US, the largest and most persistent pollution events often co-occur with extreme heat.[38] Air stagnation events, when weak winds provide little ventilation near the ground, promote pollution accumulation. Co-occurrences of heat and air stagnation are projected to increase with climate change.[39] Air pollution is also expected to worsen as the warm season lengthens, with greater pollution during the spring and autumn.[40,41] Other meteorological changes accompanying climate change may improve air quality. For example, increasing humidity may reduce ozone through chemical reactions, while increasing precipitation may remove $PM_{2.5}$ from the atmosphere (Figure 14.1).

Methane, a key GHG that contributes to near-term warming (KM 14.5), is a source of global background ozone when it undergoes chemical oxidation in the presence of nitrogen oxides.[42,43] Continued growth in methane emissions from wetlands and human activities would raise background ozone levels, including in winter (KM 3.1),[44,45] increasing the potential for a longer ozone season that begins earlier in the spring.[46] As with ozone episodes, long-term exposure to background ozone also increases mortality.[2,47]

The response of ozone and $PM_{2.5}$ to climate change—and their associated impacts on health—will vary regionally, reflecting the net balance of several complex chemical, meteorological, and small-scale processes, which vary spatially and over time (Figure 14.1).[48,49,50] Across the Midwest and Northeast, year-round ozone is expected to increase by 2035 under a very high scenario (RCP8.5).[51] In California and the Northeast, increasing temperatures under a moderate scenario (RCP4.5) would double the number of severe ozone episodes by the 2050s relative to the early 2000s,[52] with further increases in summer average ozone in these regions by 2100.[53] Projecting future $PM_{2.5}$ is complicated, as different types of $PM_{2.5}$ are expected to respond differently to changing climate.[51,54] Wildfires are expected to increase smoke $PM_{2.5}$ in the West and Alaska (KM 14.2). The rugged western topography makes it particularly susceptible to $PM_{2.5}$ increases, especially in winter when mountain valleys trap polluted air.[55] Declines in lake area in some areas of the mountainous West, driven mainly by human water use but also by changing climate, have exposed lakebeds and increased dust emissions.[56,57,58] These declines in lake area are projected to continue as temperatures rise and snowpack diminishes (KM 4.1), with further increases in dust.[59,60,61] In the arid Southwest, dust concentrations are expected to double by 2100, compared to 2010, due to warmer and drier conditions (KMs 6.1, 28.3, 28.4).[62,63] Multiple studies agree that climate change is expected to increase $PM_{2.5}$ concentrations in the Northeast.[40,49,64]

Climate Change Impacts on Ozone and Fine Particulate Matter ($PM_{2.5}$) over the United States

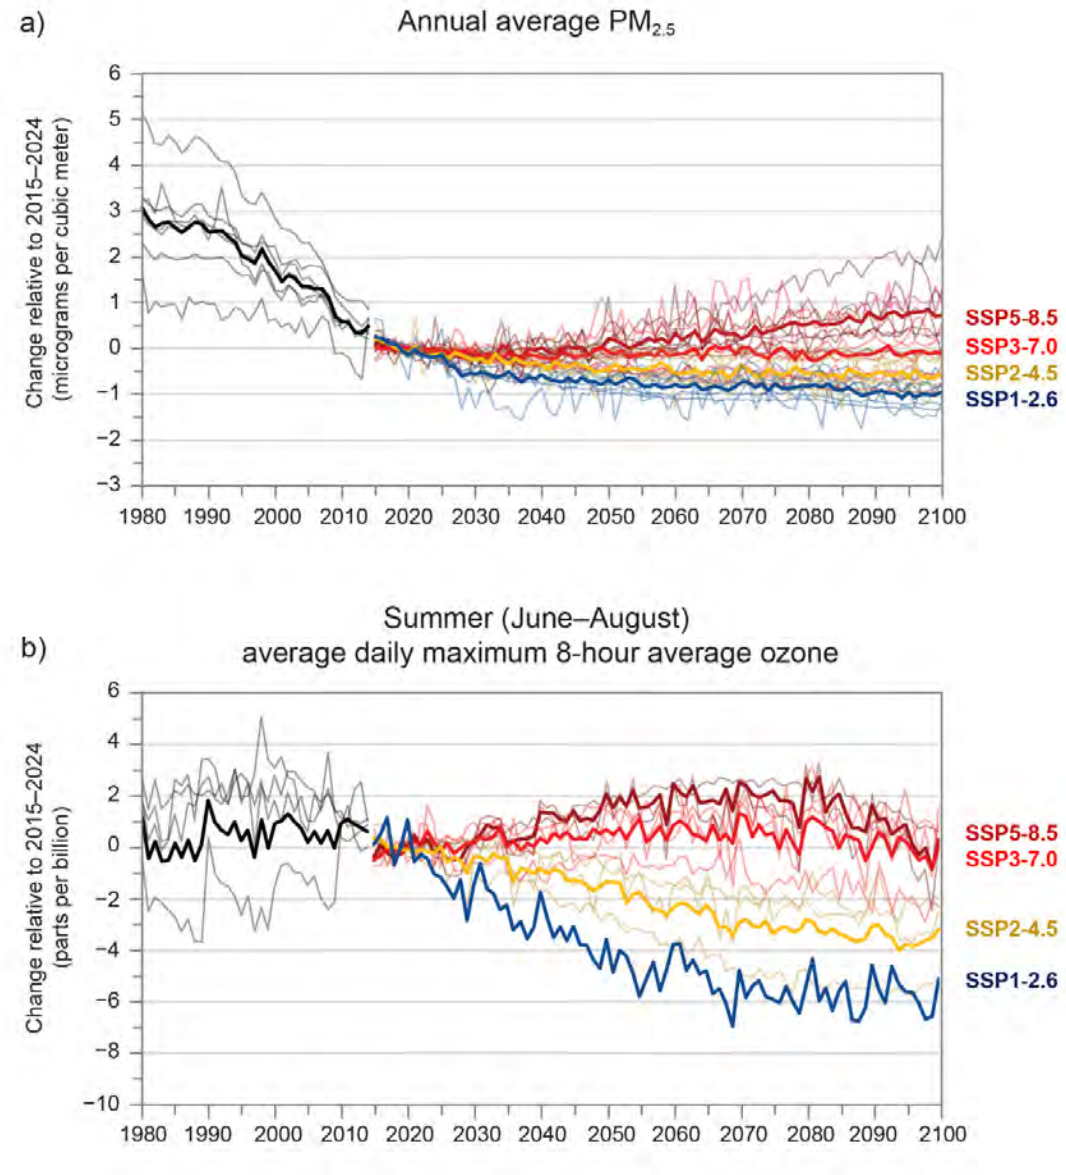


Climate change will have varying effects on ozone and fine particulate matter ($PM_{2.5}$) concentrations, including through impacts on weather-sensitive emissions.

Figure 14.1. Climate change is projected to alter concentrations of two key US air pollutants, ozone and $PM_{2.5}$, through several processes. Red icons signify increased ozone and $PM_{2.5}$, and the blue icon denotes decreased $PM_{2.5}$. Plus and minus signs indicate the expected pollutant response to climate-driven changes in meteorology. Question marks and purple icons denote uncertainty in either the response or in how the meteorological process will change with climate change. Given uncertainties and regional differences in pollution responses, the magnitude of these responses is not presented. Key Messages 14.1 and 14.2 provide more detailed descriptions of the mechanisms involved. Adapted from The Royal Society 2021[65] [CC BY 4.0].

The adverse effect of climate change on the air we breathe is known as the climate penalty on air quality, in which climate change counteracts some of the benefits expected from emissions reductions.[66] Figure 14.2 illustrates how air quality can vary under different scenarios of air pollution sources and GHGs in future decades. In general, climate change is expected to worsen air quality, although the actions that policymakers and communities take today could counteract this outcome. Steeper reductions in the human-caused emissions that contribute to ozone and $PM_{2.5}$ are expected to lessen this climate penalty and limit adverse health effects.[15,64,67,68]

Simulated Historical and Projected Changes in Fine Particulate Matter ($PM_{2.5}$) and Ozone



Reductions in human-caused emissions that contribute to ozone and fine particulate matter ($PM_{2.5}$) are expected to improve air quality in a changing climate.

Figure 14.2. Future air quality depends on both air pollution control measures and climate change. Modeled pollutant concentrations are shown averaged over the contiguous US, with the historical period in black and projections in various colors, for (**a**) annual average $PM_{2.5}$ and (**b**) summer (June–August) average daily maximum 8-hour average ozone, a metric of ozone pollution. Trends are shown relative to the 2015–2024 average value. Historical air quality improvements reflect clean air policies. Thick lines are multimodel average values. Thin lines show individual model simulations, indicating uncertainties from modeled processes and natural weather variability for each scenario. The focus on the contiguous states reflects the stronger influence from domestic emissions compared to other US regions (Alaska, Hawai'i and the US-Affiliated Pacific Islands, and the US Caribbean), where the balance of processes contributing to pollution and responses to climate change are expected to differ. These projections do not include the expected strong influence of climate change on wildfire smoke. Model simulations are described by Turnock et al. 2020.[15] Figure credit: Massachusetts Institute of Technology. See figure metadata for additional contributors.

Key Message 14.2

Increasing Wildfire Smoke Is Harming Human Health and Catalyzing New Protection Strategies

Wildfires emit gases and fine particles that are harmful to human health, contributing to premature mortality, asthma, and other health problems (*very high confidence*). Climate change is contributing to increases in the frequency and severity of wildfires, thereby worsening air quality in many regions of the contiguous US and Alaska (*likely*, *high confidence*). Although large challenges remain, new communication and mitigation measures are reducing a portion of the dangers of wildfire smoke (*medium confidence*).

Large wildfires have become more frequent in the western US in recent decades. While wildfires occur naturally, climate change and other human influences have increased their likelihood (Focus on Western Wildfires; KM 28.5; Figure A4.14).[69] Wildfires are projected to increase in many regions over the coming century (KM 27.2).[70,71,72,73] Smoke pollutants emitted by wildfires negatively impact human health, visibility, and solar energy generation.[74,75] Wildland fires are the largest contributors to $PM_{2.5}$ concentrations in some parts of the western US[74,76,77] and impact air quality across the US (Figure 14.3). These concentrations could increase, particularly in the western US, by the end of the century,[78] offsetting improvements from reduced human-caused air pollutant emissions.[71,79]

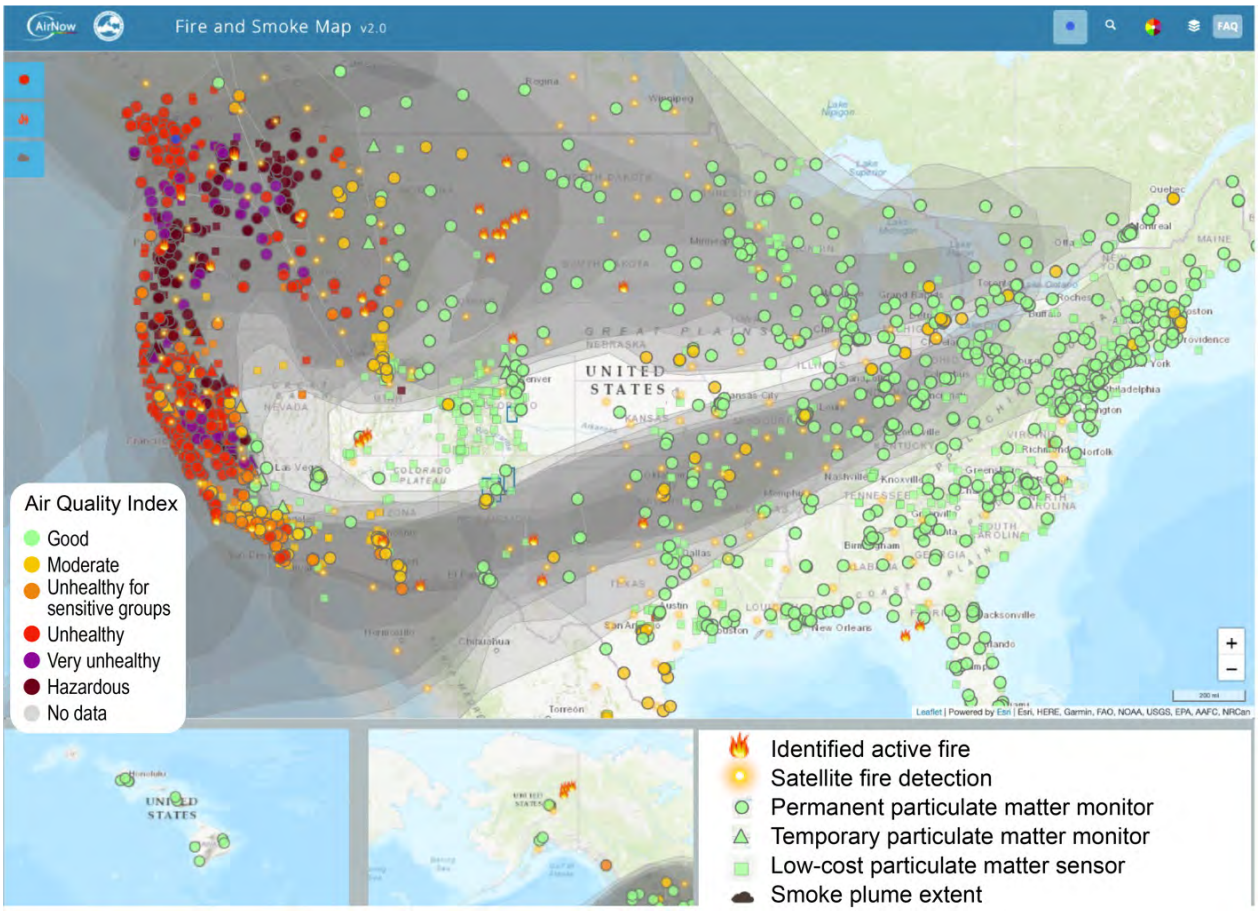
Wildfires emit $PM_{2.5}$ and other air pollutants, including volatile organic compounds (VOCs), nitrogen oxides (which contribute to ozone generation in plumes), and toxic gaseous and particulate species.[74,77] Since publication of the Fourth National Climate Assessment in 2018, studies have revealed factors influencing the smoke pollutant mixture, including the following: 1) smoke enhancements to ozone may be amplified when smoke mixes with urban pollution;[80,81] 2) chemical reactions in plumes change the composition of smoke $PM_{2.5}$ but generally not its amount;[82] and 3) hazardous VOC concentrations generally decrease with plume age due to chemical losses,[77] but structures burning in wildfires could emit additional toxic material, increasing health risks in the wildland–urban interface.[74,83,84] Finally, microbes emitted by fires and transported in smoke suggest that the region biologically affected by fires is more extensive than previously thought.[85,86,87]

Human exposure to smoke pollutants is associated with mortality, asthma, and other respiratory problems, as well as worse outcomes for birth, COVID-19 infection rates (Focus on COVID-19 and Climate Change), and emotional well-being.[88,89,90,91,92,93,94,95] Smoke exposure in the US presently contributes to 1,000–9,000 hospital and emergency department visits and 6,000–30,000 deaths annually.[96,97] Smoke can disproportionately impact certain racial, ethnic, occupational, and age-related subpopulations in both urban and rural areas (KM 22.2),[76,98,99,100] but the most impacted subpopulations are not consistent across studies. As future wildfire activity increases in some US regions, mortality rates and respiratory hospitalizations attributable to wildfires are also expected to increase (KM 27.5).[71,101]

Fire is a natural part of many ecosystems. Land managers use prescribed fire to promote ecosystem health and to reduce the vulnerability to severe fires (KMs 7.3, 28.5),[102] especially in a changing climate.[103,104] Indigenous communities have long used fire to steward their environments (KM 16.3).[105,106] Prescribed fire emissions vary greatly by region and season[107] but are typically much lower per acre than those from wildfires.[74] Prescribed fire activity could increase in some regions as land managers attempt to reduce the frequency, intensity, and spread of wildfires in a changing climate (KM 7.3).[103,104] Although air quality and health impacts are associated with prescribed fire smoke (KM 22.2),[108] well-designed prescribed fires targeted for specific locations have the potential to reduce overall smoke exposure[109] and health impacts of subsequent wildfires.[110,111]

Advances in remote sensing and improved smoke prediction systems,[112,113,114,115,116] combined with better communications strategies,[117] are helping protect the public from unhealthy smoke conditions (Figure 14.3). Smoke exposure reduction techniques, including masks and portable air filters, can help people limit the amount of $PM_{2.5}$ that is inhaled during a smoke event,[117,118,119,120,121] as well as pollen and other particulate air pollution. Smoke forecasters synthesize modeled, satellite, and monitoring data to create daily forecasts[122] that reach the general public, including underserved communities—for example, through Spanish translations. Communication of these forecasts and techniques to reduce smoke exposure occurs through interagency federal,[117,123] state, and Tribal programs, as well as social media. However, people tend to take protective actions, such as staying indoors and using air filters, in response to symptoms from exposure rather than take preventive measures.[124] More work would be needed to quantify and communicate the benefits of exposure-reduction actions.[125,126]

Impacts of Wildfire Smoke on Air Quality



Wildfire smoke affects air quality across the country.

Figure 14.3. Wildfire smoke can affect the daily lives of people across the country, as communicated in real time to the public on September 13, 2020, on the AirNow Fire and Smoke Map (https://fire.airnow.gov/). Monitors measuring particulate matter are color-coded by air quality index from green for good air quality to brown for hazardous. Here, unhealthy to hazardous air quality conditions are shown at multiple monitors (circle, triangle, and square icons) across the western US, and satellite imagery (gray) shows smoke extending across much of North America. On this day, the US Caribbean was free of smoke, and monitor or sensor data were not yet available, so the region is not shown. Data are not available for US-affiliated Pacific Islands. Adapted from EPA 2022.[127] Base map: Copyright © 2022 Esri and its licensors. All rights reserved.

Key Message 14.3

Air Pollution Is Often Worse in Communities of Color and Low-Income Communities

Communities of color, people with low socioeconomic status, and other marginalized populations are disproportionately harmed by poor air quality (*very high confidence*). In the coming decades, these same communities will, on average, face worsened cumulative air pollution burdens from climate change–driven hazards (*very likely*, *high confidence*). Decision-making focused on the fair distribution of air quality improvements, rather than on overall emissions reductions alone, is critical for reducing air pollution inequities (*high confidence*).

Air pollution disproportionately affects people of color and people with low socioeconomic status in both cities and rural places.[128,129,130,131] While air quality has improved over recent decades, air pollution disparities have persisted.[132,133,134,135,136,137] There is a clear pattern of more air pollution sources being located in communities of color and low-income neighborhoods. Diesel traffic exhaust is among the largest sources of air pollution inequalities in urban areas,[138] while other emitters, including industrial facilities,[25,139] prescribed agricultural burns,[140] concentrated animal feeding operations,[141,142,143,144,145] power generation,[146] and oil and gas infrastructure,[147,148] contribute to air pollution disparities in cities and rural environments. Racism in historical practices and policies has contributed to ongoing inequities, protecting White areas from pollution and disinvesting in and off-loading those costs onto communities of color, for example, through redlining and housing segregation.[149,150,151]

The health impacts of the unequal distribution of air pollution are magnified by factors including reduced access to nutrition, social and institutional support, and healthcare, as well as psychosocial stress from racism and poverty.[152] As a result, a given level of air pollution can cause more harm to people of color and those with lower socioeconomic status.[30,152,153,154] Environmental inequalities often overlap, such as exposure to both poor air quality and higher-than-average urban heat (KM 21.3).[155,156] Exposure to air pollution and high air temperatures in combination can worsen health outcomes.[29,30,157,158] Environmental inequalities also often compound in ways that exacerbate negative impacts; for example, reduced tree cover, common in urban communities of color,[159] intensifies urban heat (KM 12.2) and affects air quality (KM 14.1). Disparities in air-conditioning access[160,161] and other housing differences may increase infiltration of outdoor air pollution and wildfire smoke into homes and schools in communities of color and lower-income neighborhoods,[162] and low-income households may have less ability to adopt in-home air filtration.

A 3.6°F (2°C) increase in average global temperatures relative to the 1986–2005 average is projected to worsen $PM_{2.5}$-related premature mortality for African Americans over age 65 by 40%–60% more than for people of other racial and ethnic groups.[155] This same temperature change is projected to cause substantially higher rates of $PM_{2.5}$-related asthma for African American children and smaller, but still disproportionate, increased rates for Latino, Asian, Pacific Islander, and American Indian and Alaska Native children. In New York City and Newark, New Jersey, projected trends in air stagnation are expected to worsen inequalities in concentrations of nitrogen dioxide (NO_2),[163] an air pollutant associated with asthma.[164,165] The impact of climate change on air quality–related inequalities may differ depending on the sources of pollution and whether pollutants are emitted directly or formed through chemistry (KM 14.1). However, climate change can increase cumulative and unequal air quality–related health burdens, such as from the combined effects of air pollution and temperature, even if air pollution itself does not worsen.[29,30,157,158]

Actions to address climate change through GHG regulation will also affect air quality, with the distribution of benefits dependent on the mitigation approach. Programs focusing on GHG sources with the lowest mitigation costs have had mixed impacts on air pollution equity.[166,167] In California, GHG regulation through carbon cap-and-trade increased emissions of combustion-related air pollutants in communities of color

and low-income neighborhoods.[168] Approaches focused on lowering aggregate emissions across a large geographic region, or from a single emissions category, have been shown to be less effective than interventions aimed at reducing air pollution inequalities for a specific location.[169] Solutions can be designed to reduce disparities and overcome the challenges associated with GHG regulation.[170,171]

Box 14.1. Environmental Justice, Air Pollution, and Climate Change: Houston, Texas

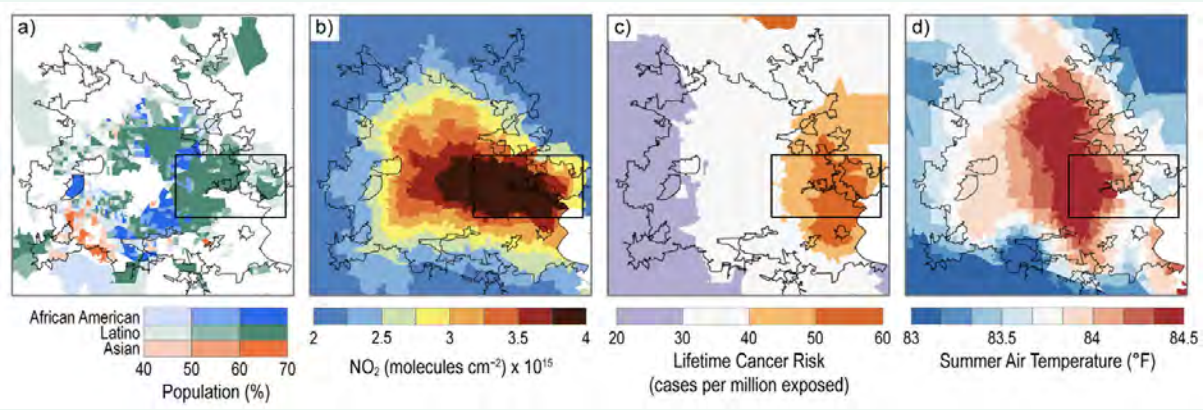
Houston's Ship Channel region is a patchwork of chemical refineries, freeways, homes, and playgrounds (Figure 14.4; Box 26.1). Air pollution levels along this busy industrial waterway, connecting downtown Houston to Galveston Bay, are among the highest in the city (Figure 14.5). Flares and odors are commonplace,[172,173,174] and community concerns about health impacts are often ignored. Many of Houston's African American, Latino, and working-class families live in the neighborhoods of the Ship Channel, where they are more likely to breathe harmful cancer-causing air pollution from diesel trucks and refineries.[138,175,176,177,178,179,180] Communities living at the fenceline of the petrochemical industry face ongoing vulnerabilities, such as dual exposure to air pollution and heat and endangerment from damages to petrochemical facilities caused by stronger hurricanes (KMs 9.2, 15.2). In 2017, Hurricane Harvey triggered widespread industrial releases of hazardous air pollutants throughout the Houston Ship Channel.[181,182,183] Houston is also the stage for foundational scholarship on environmental justice by Dr. Robert Bullard (KM 20.3), where community organizations lead work to reduce air pollution and make communities more resilient to climate change.

Air Pollution Exposure at Home in the Houston Ship Channel Region

Industries expose people living near the Ship Channel—often African American, Latino, and low-income residents—to harmful air pollution.

Figure 14.4. Nighttime industrial flaring exposes residents to air pollution near the Houston Ship Channel in the Deepwater community in Pasadena, Texas, a primarily African American, Latino, and low-income neighborhood. Photo credit: ©Cassandra Casados-Klein, Air Alliance Houston.

Air Pollution and Temperature Inequalities in Houston, Texas



Air pollution, its health impacts, and temperatures are unequally distributed across Houston, Texas.

Figure 14.5. Air quality and temperatures vary across Houston, Texas (urbanized area outlined in black). (**a**) For each neighborhood, the largest racial or ethnic group is shown: African American (blue), Latino (green), and Asian (orange). Higher-than-average levels of (**b**) nitrogen dioxide (NO_2; in 2019), (**c**) lifetime cancer risks associated with chronic air pollution exposure per million equally exposed people (2018), and (**d**) summer (June–August) air temperatures (2020) are found in neighborhoods that are primarily African American and Latino, especially those surrounding the Ship Channel (black box). There is variability in time and at very fine spatial scales that may not be captured here. Figure credit: University of Virginia, Columbia University, and Montana State University.

Key Message 14.4

Climate Change Is Worsening Pollen Exposures and Adversely Impacting Health

Increased allergen exposure damages the health of people who suffer from allergies, asthma, and chronic obstructive pulmonary disease (COPD) (*very high confidence*). Human-caused climate change has already caused some regions to experience longer pollen seasons and higher pollen concentrations (*very likely, high confidence*), and these trends are expected to continue as climate changes (*very likely, high confidence*). Increasing access to allergists, improved diagnosis and disease management, and allergy early warning systems may counteract the health impacts of increasing pollen exposure (*high confidence*).

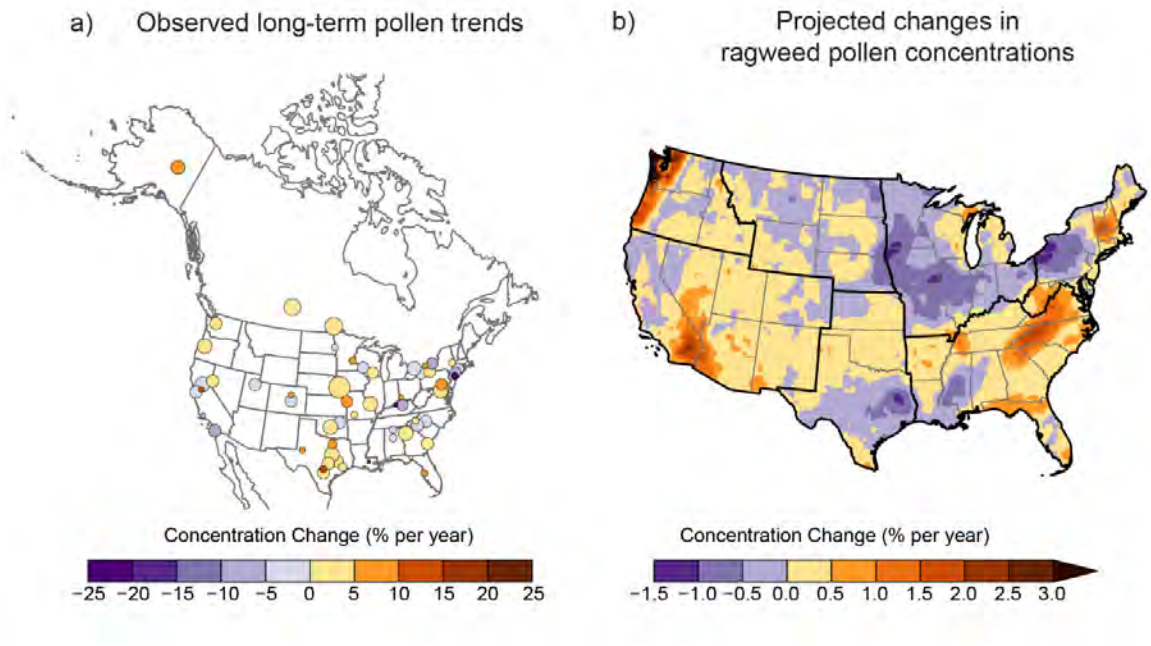
Allergic airway disease, including allergic rhinitis and asthma, is widespread in the US, is becoming more prevalent, and imposes a burden of several billion dollars in healthcare costs and lost productivity annually.[184] Exposure to allergenic pollens and molds (aeroallergens) triggers allergic disease development.[185,186,187] Co-exposure to aeroallergens and pollutants like ozone, nitrogen oxides, and $PM_{2.5}$ can exacerbate allergic airway disease symptoms.[188,189,190] Aeroallergen exposure can compromise the body's antiviral defenses, possibly increasing susceptibility to respiratory viral infections in both allergic and nonallergic people.[186,191] It is also probable that pollen exposure is associated with COPD mortality.[192] Pollen can also transport viruses.[193]

Local climate affects emissions of allergenic tree and grass pollens and fungal spores. Climate change is altering pollen season characteristics for allergen-producing trees during spring and for grasses and weeds during summer and fall.[194] Rising atmospheric carbon dioxide (CO_2) can increase pollen allergenicity.[195,196,197]

Multiple US regions have experienced longer, more intense pollen seasons, with earlier start dates and increased emissions and airborne loads over the past 30 years, increasing the potential for exposures (Figure 14.6; KM 22.2).[187,194,196,198,199,200,201] For example, the season for ragweed pollen, a significant allergen, has lengthened since the 1990s (Figure A4.13), and its range has expanded northward;[202] ragweed grows faster, flowers earlier, and produces more pollen in high-CO_2 areas.[196,203] With climate change, ragweed pollen is projected to increase in most regions (Figure 14.6) and to co-occur with high ozone more frequently.[204,205] Likewise, the number of days with total pollen concentrations exceeding thresholds for triggering allergies is projected to increase in most US regions.[204,206,207,208]

Increasing frequency and intensity of heatwaves, storms, and floods associated with climate change can also intensify aeroallergen exposures. Mold proliferation is increased by floods. Thunderstorms can exacerbate respiratory allergy and asthma in patients with hay fever, and similar phenomena have been observed for molds.[209]

Observed and Projected Pollen Changes Under Climate Change



Pollen has been increasing in many US regions and is projected to continue to increase as climate changes.

Figure 14.6. (**a**) Observed long-term pollen increases are shown as the linear trend of total annual pollen at 60 stations (1990–2018). (**b**) Modeled projected changes in average airborne ragweed pollen concentrations in 2047, relative to 2004, are shown for climate change conditions under a very high scenario (RCP8.5). Yellow and red shades indicate increases in pollen concentrations, and circle size in panel (a) reflects the number of years of data at each station. Observations are not available for many US states and affiliated territories, and the modeled projection does not include non-contiguous US states and territories. There is a net increase in concentration overall, with marked increases in certain areas and declines in others. (a) Adapted from Anderegg et al. 2021[194] [CC BY 4.0]; (b) adapted from Ren et al. 2022[210] [CC BY 4.0].

Allergic airway disease is underdiagnosed, and many therapies are underutilized.[211] Increasing access to allergists and diagnostic tests can help clarify what exposures drive allergies for individuals and aid in developing therapeutic plans including medical and immune therapies.[212] Staying indoors and wearing masks to reduce exposure, as well as avoidance of allergens through early warning systems[213] and other public health campaigns, can also reduce impacts.[214] Understanding of climatic influences on pollen exposures can inform diagnosis and disease management, but it remains unclear whether these and other advances can blunt the health impact of increased aeroallergen exposures as the climate warms.

Key Message 14.5

Policies Can Reduce Greenhouse Gas Emissions and Improve Air Quality Simultaneously

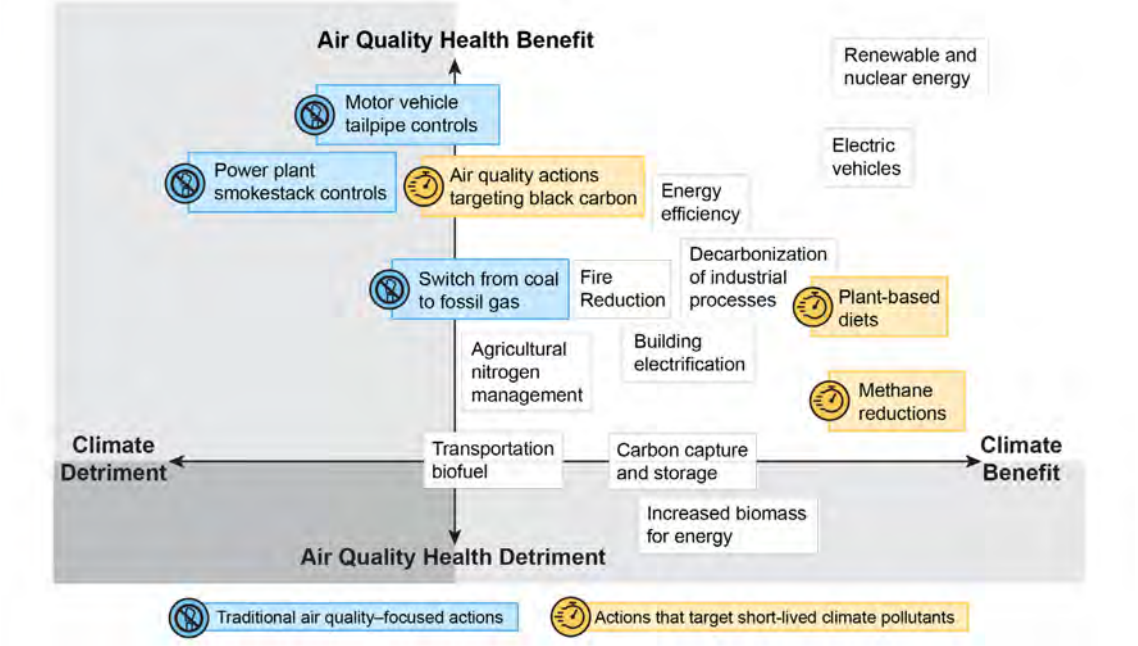
Substantial reductions in economy-wide greenhouse gas emissions would result in improved air quality and significant public health benefits (*very likely*, *high confidence*). For many actions, these benefits exceed the cost of greenhouse gas emission controls (*likely*, *high confidence*). Through coordinated actions emphasizing reduced fossil fuel use, improved energy efficiency, and reductions in short-lived climate pollutants, the US has an opportunity to greatly improve air quality while substantially reducing its climate impact, approaching net-zero CO_2 emissions (*high confidence*).

Fossil fuel energy use is responsible for 92.1% of US CO_2 emissions[215] and the majority of $PM_{2.5}$-induced deaths.[20,216] Consequently, actions to control GHGs, including reductions in energy demand or shifts toward cleaner energy sources, typically reduce air pollutant emissions from the same sources, benefiting air quality and health.

By contrast, actions that have substantially improved US air quality since 1990 generally did not reduce GHG emissions, as they focused on technologies that remove air pollutant emissions from power plants, industrial facilities, and vehicles but do not reduce fossil fuel consumption—and some actions increased fossil fuel use and GHG emissions (Figure 14.7).[215,217,218] In the past decade, fuel switching from coal toward renewables (wind and solar) and lower-emitting sources (fossil gas) has reduced emissions of both GHGs and air pollutants.[219,220]

To further improve air quality, more stringent smokestack and tailpipe controls on fossil fuel sources may be chosen. Alternatively, GHG mitigation scenarios that meet the long-term temperature goal of the Paris Agreement and approach net-zero emissions this century replace fossil fuels with cleaner energy sources and reduce overall energy use (Figure 14.7; KM 32.2).[221,222,223] This clean energy transition would provide air quality[224] and health benefits[225] beyond what smokestack and tailpipe controls can provide.

Potential for Emissions-Reduction Actions to Achieve Air Quality and Climate Benefits

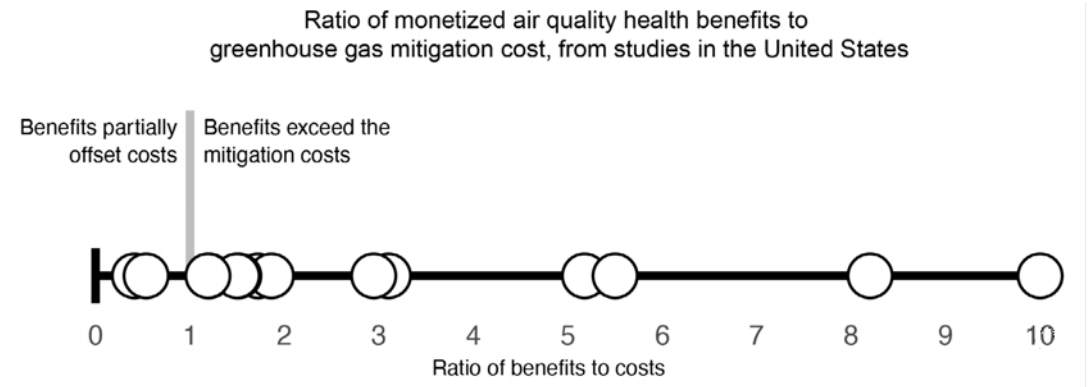


Many emissions-reduction actions can achieve multiple benefits for climate, air quality, and health.

Figure 14.7. Environmental policies to mitigate emissions will affect both air quality and climate change, and actions can be coordinated to address both problems simultaneously. Blue boxes show mitigation actions aimed at conventional air pollution controls; orange boxes show actions targeted at short-lived climate pollutants; and white boxes show other types of actions. Emissions-reduction actions in the upper right have greater air quality and climate benefits. Box position indicates the relative potential of actions, from most detrimental to most beneficial, and should not be interpreted quantitatively (e.g., that one action has twice the potential of another). The size of the boxes indicates some uncertainty, with actions in boxes straddling an axis being uncertain in the direction of the effect. Addressing climate change requires moving to the actions on the right-hand side of the figure, where many options simultaneously improve air quality. Figure credit: EPA, University of North Carolina at Chapel Hill, and Duke University.

Economy-wide GHG reductions are expected to decrease emissions of air pollutants emitted from the same sources, resulting in benefits for air quality and health (KMs 13.3, 32.4).[226,227,228,229,230] Each metric ton of CO_2 reduced is estimated to bring about health benefits[231] that are valued in 26 US studies from $8 to $430 (in 2022 dollars), with a median of $100 per ton of CO_2 (see Traceable Accounts for details on relevant studies), mainly from avoided premature death. These health benefits can significantly offset or exceed implementation costs for many GHG mitigation measures (Figure 14.8). Since health benefits exceed costs in most studies, these GHG reductions are economically beneficial, even without accounting for other benefits of slowing climate change. Estimates of these benefits vary across many studies because of differences in mitigation actions considered, methods of assessing emissions, pollutant concentrations and health impacts, and mortality valuation.[232] Most studies have typically evaluated mortality while neglecting morbidity impacts, such as preterm births, restricted activity days, and hospitalizations,[233] and therefore may underestimate the full health benefits of GHG reductions. However, some individual actions, including biomass energy and carbon capture and storage, may provide small air quality benefits or even worsen air quality (Figure 14.7; KM 5.3).[234] Lastly, GHG mitigation policies may alleviate or worsen inequities in air pollution exposure, depending on their design (KMs 14.3, 32.4).

Air Quality and Health Benefits Estimates in the US, Relative to Costs



Air quality health benefits alone exceed or significantly offset the costs of greenhouse gas reductions.

Figure 14.8. Controls on greenhouse gas (GHG) emissions also reduce air pollutant emissions from the same sources (often fossil fuel combustion), improving air quality and saving lives. Each circle denotes the results from a study in the US during 2013–2022. These studies find that the value of health benefits significantly offset or in most cases exceed the GHG emissions control costs, apart from other benefits of slowing climate change. Figure credit: EPA, University of North Carolina at Chapel Hill, and Duke University.

The air quality benefits of GHG controls by reducing co-emitted air pollutants occur mainly locally and regionally and nearly immediately following emissions reductions.[19,235] By contrast, benefits of slowing climate change, including lessening the impacts of climate change on air quality (KM 14.1), are long term and distributed globally. Recognizing these air quality health benefits strengthens incentives for local, state, and national actions to reduce GHG emissions.[236]

Indoor air quality can also be affected by GHG reduction actions, as some methods for improving building energy efficiency decrease ventilation, which can increase mold and degrade indoor air quality.[237] Newer approaches to building design improve energy efficiency while meeting temperature control and indoor air quality needs.[238] More widespread application of these approaches can reduce energy use, mitigate GHG emissions, and improve indoor air quality (KM 12.3).

Climate mitigation actions focused on short-lived climate pollutants (SLCPs) can also improve local air quality. Reducing SLCPs, including methane, black carbon, and ozone, directly improves air quality and reduces the near-term rate of warming, affecting climate more quickly than reductions in long-lived GHGs like CO_2.[239,240] Methane directly contributes to warming and increases ozone air pollution globally.[42,241] The social cost of methane is estimated at around $2,200 (in 2022 dollars) per metric ton[242] when accounting for impacts via climate change. Other estimates that also include health impacts of ozone are higher (about $4,600 to $9,200 per metric ton in 2022 dollars), with over half of that from ozone health impacts.[243,244,245] VOCs and carbon monoxide (CO) form ozone in the atmosphere, and reducing their emissions benefits both climate and air quality. Nitrogen oxides also contribute to ozone but have a net cooling influence by shortening methane's lifetime and forming $PM_{2.5}$.[240,246] Together, global emissions of methane, VOCs, CO, and black carbon have contributed about 1.5°F to global average warming in 2019, compared to about 1.4°F from CO_2 increases (KM 3.1).[247]

Most forms of $PM_{2.5}$ cool the climate, and removing them exacerbates climate warming (KMs 2.1, 3.1), as seen from historical sulfur dioxide reductions to improve air quality.[248,249,250,251] If $PM_{2.5}$ reductions are undertaken together with CO_2 and SLCP reductions, this short-term warming may be outweighed, leading to a net cooling.[252,253] Carbon particles, mostly from fires and burning fossil fuels, cause a mix of warming and cooling effects.[240] Of these, black carbon is the component that contributes most to warming, and actions targeting

sources that emit relatively more black carbon, like diesel engines, are expected to best reduce warming while improving air quality. Ammonia, which contributes to $PM_{2.5}$ and is growing in relative importance as a $PM_{2.5}$ source, comes mostly from agriculture.[254] Agricultural ammonia and methane emissions can be reduced by more efficient use of fertilizer[255,256] and adopting healthier plant-based diets.[244,257] Finally, air pollutants can influence regional climate such as through changes in clouds and precipitation, and black carbon can increase snowmelt, which affects water resources (KM 4.1).[258]

Traceable Accounts

Process Description

Authors were selected to provide diversity in topical focus areas and to align expertise with the anticipated topics for the chapter, as well as for geographic and racial diversity. All authors are recognized experts in climate change and air quality, including in the focus areas of the chapter.

The author team met online roughly every two weeks to discuss the organization of topics, main points to emphasize, and the many logistical questions related to writing the chapter. The author team agreed on five key topics as the focus of the chapter, reflected in the Zero Order Draft (ZOD). The ZOD was made publicly available, and a public engagement workshop was held on January 18, 2022, where the author team gathered public comments on the ZOD. All written public comments on the ZOD were reviewed by the author team, and responses were provided for each. Similarly, the author team responded to comments received on multiple drafts that followed.

Key Messages were developed by small author teams, who were responsible for developing the content of each topic area, and discussed among all authors. The team achieved consensus on the wording of the Key Messages for the Third Order Draft through group meetings to discuss this text specifically. Following comments on drafts of the Fourth Order Draft, the team made small revisions to the Key Messages, and these were discussed among authors to again achieve consensus.

Key Message 14.1

Climate Change Will Hamper Efforts to Improve US Air Quality

Description of Evidence Base

An extensive literature base documents air quality modeling of the response of ozone and fine particulate matter ($PM_{2.5}$) to future climate change. Comparison across studies, however, is challenging due to the use of different scenarios, time periods, metrics, and process representations in the modeling systems. The chemistry of both ozone and $PM_{2.5}$ is complex, which adds to the difficulty of predicting the influence of climate change on air quality. Source gases of ozone and $PM_{2.5}$ include methane, carbon monoxide, nitrogen oxides, non-methane volatile organic compounds, sulfur dioxide, ammonia, and dimethyl sulfide; types of $PM_{2.5}$ directly emitted into the atmosphere include black carbon, organic carbon, mineral dust, sea salt, pollen, and spores.

The literature using observations to infer process-level relationships between air pollutants and climate is growing and includes links with temperature, precipitation, winds, and near-surface mixing.[39,259,260] However, observational records are relatively short (a few decades at best), and isolating responses to meteorology requires disentangling air pollution responses to large emissions perturbations over the observing period to reveal the influence of climate change and variability. Air pollution trends in recent decades in some urban areas and at the regional scale are well established based on high-quality monitoring.[13,261] A large literature base employs a wide range of methods to attribute observed trends and variability to anthropogenic emissions versus meteorological variability. Highly resolved spatial distributions needed to assess community-level exposure are sparse but growing, and new observations from satellites and low-cost sensors will prove useful in this regard. For example, the Tropospheric Emissions: Monitoring of Pollution (TEMPO) satellite instrument, launched in April 2023, promises to provide hourly, fine-spatial information about US pollution.[262,263]

Many processes involving interactions between climate and air quality have been the foci of major lab, field, and modeling efforts (e.g., wildfires) or represent fundamental physics (e.g., the increase in water vapor as temperatures rise), and new work since the Fourth National Climate Assessment (NCA4) was published in 2018 further strengthens this deep evidence base. Such processes and their impacts on air pollution in a changing climate are illustrated in Figure 14.1. Wildfires are a key example of how feedbacks from the biosphere are expected to increase air pollution in future years (KM 14.2).[264] An increased frequency of heatwaves will also lead to more extreme levels of ozone and $PM_{2.5}$ (KM 2.2),[38,265,266] while warmer average temperatures will increase seasonal mean daily maximum 8-hour average (MDA8) ozone and $PM_{2.5}$ concentrations.[49,51,260] The source gases of ozone and $PM_{2.5}$ from plants and soils are expected to increase with warmer and drier conditions,[259,267,268,269] thus degrading air quality. In addition, as plants wither and die during drought, ozone that would otherwise be deposited on leaves may accumulate in the atmosphere,[270,271] although this process is less well studied. Other processes may lead to lower pollution in a warmer climate. Some studies project that annual average precipitation, which removes $PM_{2.5}$, will increase across much of the United States by 2100,[272] but not all studies agree.[273] Basic physics explains why atmospheric humidity will rise with temperature, and the chemical reactions governing ozone destruction will increase with humidity, reducing ozone in unpolluted regions.[68,274] In contrast, greater humidity is expected to worsen $PM_{2.5}$ air quality in some regions.[275] Finally, future trends in the regional transport of pollution or in the frequency of weather patterns like stagnation will have consequences for US air pollution, but these trends are not well established across the US.[276,277,278]

Efforts to model the net response of US air quality to climate change have taken two main approaches, with some studies focusing on the impact from climate change alone[27,41,49,50,51,52,68,279] and other studies including the influences of both climate change and changing emissions from human sources of ozone and $PM_{2.5}$, such as fossil fuel combustion.[26,39,45,67] Some studies compare the combined effects of emissions and climate change with climate change alone.[44,46] There is general agreement across these studies that climate change will degrade US air quality in many regions with high concentrations of pollutants. Summertime average surface ozone is expected to increase across much of the northern and eastern United States[26,51] and during heatwaves in populous areas already affected by pollution.[53] Surface $PM_{2.5}$ is also projected to increase in areas prone to wildfires (KM 14.2) or dust events,[63] but there is less agreement on the response of $PM_{2.5}$ elsewhere.[50,51,54,280]

Many epidemiological health studies have identified a wide range of adverse health outcomes following exposure to wildfire smoke and dust, as well as to ozone and particulate matter. Such adverse outcomes are expected to generally increase in response to ongoing climate change.[26]

Major Uncertainties and Research Gaps

Uncertainties remain in how meteorology will respond to climate change in different regions of the United States and how these meteorological responses, in turn, will trigger changes in different air pollutants. While it is well established that rising methane will increase background ozone at the surface, there is uncertainty in the spatial patterns of this response tied to nitrogen oxides emissions, including from ship plumes.[42,281] Climate variability tends to dominate the uncertainty in shorter-range projections (thin lines in Figure 14.2).[282,283,284] Health responses to the combined impacts of exposure to multiple pollutants and other climate change impacts (heat, flooding) are not well quantified. Extensive research into the relative toxicity of $PM_{2.5}$ mixtures has not consistently shown that any particular source or component is more strongly related to health effects than total $PM_{2.5}$ mass.[285]

The lack of systematic information available from chemistry–climate models for US air quality complicates the assessment of future change. For example, Figure 14.2 makes use of the most comprehensive set of coordinated simulations with international climate models that include the atmospheric chemistry necessary for projections of future air quality. There are different numbers of models with simulations

available for each scenario. Specifically, seven models simulated $PM_{2.5}$ for both the historical simulations and four future air pollutant emissions and climate scenarios during 2015–2100 (see Table 3 in the Guide to the Report). In contrast, for ground-level ozone, fewer models (one to five depending on scenario) archived the hourly ground-level ozone needed to calculate the MDA8 metric used to assess compliance with the National Ambient Air Quality Standards. In Figure 14.2, thick lines show the average of all available model simulations for each scenario, with each simulation shown individually by the thin lines. A list of the individual models that produced each scenario in Figure 14.2, together with the simulated fields, are available in the metadata. Models and simulations are further described by Turnock et al. (2020).[15]

In more recent studies, progress is being made in quantifying different sources of uncertainty in emissions scenarios and future projections for US air quality, including separately determining the uncertainty associated with model mechanisms and with naturally arising climate variability.[259,286,287]

Description of Confidence and Likelihood

The overall assessment of *medium confidence* that climate change is projected to worsen US air quality in many US regions reflects uncertainty in the net ozone and $PM_{2.5}$ responses to climate change across different regions.[48,49,50,51,54,68,280] The evidence for air pollution impacts on health is well established from epidemiological and toxicological studies,[4,7,9,10] supporting a *very likely*, *high confidence* assessment. There is *very high confidence* and it is *very likely* that climate change will increase the intensity and frequency of extreme heat (KM 2.2).[247] Observational evidence, theoretical understanding, and modeling studies all support an assessment of *high confidence* that increasing frequency of warmer and drier conditions will *very likely* raise the risk of exposure to airborne dust and wildfire smoke in some regions.[62,63,69,288]

Key Message 14.2

Increasing Wildfire Smoke Is Harming Human Health and Catalyzing New Protection Strategies

Description of Evidence Base

This section was based on a review of the recent peer-reviewed literature. Many studies detail the harmful health effects of wildfire smoke on human health. A growing weight of evidence indicates that wildfires and associated air quality impacts will increase in the future with a warming climate, but the interactions are complex and regionally driven. Our understanding of smoke exposure and health impacts has been aided by combinations of surface and satellite-based observations, as well as model simulations.[289,290] Smoke prediction (forecast) systems are a useful mitigation tool,[121] and the number of them online, along with many science improvements, has grown in recent years across North America.[112,114,115,291,292,293,294]

Since NCA4, particularly impactful wildfire smoke years have driven the development of new communication and smoke mitigation measures. The authors highlight the growing base of information on how the public can protect itself before and during a wildfire, such as that found in the EPA Smoke-Ready Toolbox (https://www.epa.gov/smoke-ready-toolbox-wildfires), as well as the development of wildfire smoke mitigation programs by many states and Tribes, in addition to federal programs.[295,296,297,298] Evidence shows that social media plays an important role in communicating mitigation measures. For example, smoke blogs in many western states are a nexus of information.[299,300,301,302]

Major Uncertainties and Research Gaps

Uncertainties in future smoke exposure are intrinsically tied to the uncertainties in future wildfires. Hence, improvements in future wildfire projections will reduce uncertainties in future smoke exposure. Related to this is the uncertainty regarding how future use of prescribed fire as a management tool for wildfire

mitigation and ecosystem health will affect smoke at regional and national extents. Finally, quantification of how Indigenous fire practices influence smoke both historically and into the future will also reduce this uncertainty.

Uncertainties remain in our understanding of the health effects of smoke-specific particulate matter and the impacts of cumulative smoke exposure over many years. Research investigating indoor concentrations during wildfire smoke events is preliminary, and there is a specific need to understand how indoor concentrations vary between socioeconomic groups during wildfire smoke events. Research quantifying the effectiveness of smoke mitigation measures and other health protection interventions is limited, and relying on personal interventions such as wearing face masks, filtering indoor air, and staying indoors can have limitations.[303,304]

Description of Confidence and Likelihood

There is *very high confidence* that wildfires emit gases and fine particulate matter that are harmful to human health based on epidemiological and toxicological studies.[74,77,88,89,90,91,92,93,94,95] Many studies document the effects of short-term acute exposures on respiratory healthcare outcomes (Liu et al. 2015; Reid et al. 2016[92,93] and references therein). Less quantified but also of concern are the effects of long-term lower-level exposure.[92,93] A growing weight of evidence supports the *likely*, *high confidence* assessment that with a warming climate, wildfires and associated air quality impacts will increase in the future in many regions of the contiguous US and Alaska, but the fire-climate interactions are complex and regionally driven, and the extent to which human management actions will influence future wildfire activity is unknown (Ch. 7). Since NCA4, particularly impactful wildfire smoke years have driven the development of new communication and smoke mitigation measures.[117,118,119,120,121] Advancements in the science in models and observational data are also leading to products to help inform the public.[112,113,114,115,116,154] However, these developments may not be enough to substantially reduce exposure, especially for all demographic groups.[125,126] This uncertainty in exposure reduction leads to the assessment of *medium confidence* in the efficacy of these measures and the conclusion that challenges remain.

Key Message 14.3

Air Pollution Is Often Worse in Communities of Color and Low-Income Communities

Description of Evidence Base

This section is based on a review of peer-reviewed scientific literature, focusing on work published in the last decade. It has been repeatedly shown that communities of color, low-income communities, and other marginalized groups are disproportionately exposed to and harmed by air pollution.[25,30,132,133,134,135,136,137,138,139,140,141,142,143,144,145,146,147,148,152,153,154,155] Over the last 10 years, there has been an emphasis on developing and applying new measurements and models to describe air pollution inequalities and, in some cases, on deepening commitments to community-engaged scholarship. Improved monitoring and modeling have advanced tools for distinguishing pollutant differences within and between neighborhoods, whereas research over previous decades was largely based on analyses of source proximity and/or health impacts. A new generation of sensors, costing a few hundred dollars each, is supporting collaborative air quality and exposure research and producing actionable results.[305,306,307,308,309,310,311] In addition, recent advances in satellite remote sensing are enabling more detailed observations of neighborhood-level pollution inequalities, with satellite measurements being used directly in the case of nitrogen dioxide (NO_2)[138,163,177,312] and in combination with models for $PM_{2.5}$ and NO_2,[133,134,135,313,314] with additional information, especially on daytime temporal variability, anticipated with the launch of TEMPO. Machine learning and regression models are filling observational gaps and improving estimates of unequal exposures.[129,134,313,315] Current understanding of air pollution health

impact disparities is also improving through neighborhood-level datasets on disease rates.[133,314] Chemical transport models, which are standard research and air quality decision-making tools that account for key chemical and physical processes, have only begun to be used for neighborhood-level environmental justice applications because of model resolution challenges.[316,317] That said, neighborhoods are typically larger than the spatial gradients of primary pollutants, and emissions sources are often clustered in overburdened communities. As a result, models with very-fine-scale spatial resolution (hundreds of meters) may not always be needed to describe neighborhood-level inequalities,[163,318] further opening the range of tools applicable to describing and understanding air pollution inequalities. As air pollution datasets evolve, they reinforce what communities with environmental justice concerns have been saying for decades.

Major Uncertainties and Research Gaps

While patterns of inequities related to air pollution sources, exposure, and associated adverse health impacts are well established, we lack tools that fully describe neighborhood-level distributions of a wide variety of pollutants harmful to health, such as air toxins, and of pollutant mixtures. Air pollution exposures also occur in the home, in classrooms, and at work, and there is little research simultaneously considering outdoor, indoor, and occupational exposures. To date, researchers have largely focused on producing high spatial resolution air pollution maps, and as a result, there is far less knowledge of the temporal variability and source patterns driving air pollution inequalities. Without also capturing this temporal variability, it is difficult to incorporate issues of inequalities in broader air quality and climate change decision-making.[163] Equity-related questions are not a common feature of air pollution–climate research, partly because of computational limitations on model spatial resolution and partly because of disciplinary and regulatory divides in the fields of air quality and environmental justice. There is limited research on how greenhouse gas (GHG) mitigation actions have differential impacts on air quality affecting different communities, but there is clear evidence that without considering equity, GHG regulations can adversely affect air quality in communities of color and communities with low-socioeconomic status.[168]

Description of Confidence and Likelihood

There is *very high confidence* that communities of color, low-income communities, and other marginalized populations, on average, live in greater proximity to emissions sources, experience higher levels of air pollution, and are disproportionately harmed by poor air quality[25,129,138,152,153,319]—this has been repeatedly shown for decades. The author team assigns *very likely*, *high confidence* to the statement that these same communities will disproportionately face worsened cumulative air pollution burdens from climate change–driven hazards. Regarding the likelihood, there are two facets to consider concerning how climate change will affect air pollution inequity: 1) how the amount and distribution of air pollution will differ in the future and 2) how the health impacts of air pollution exposures will vary with climate change. There is less research on how the amount and distribution of air quality (i.e., air pollution inequalities) will change in the future,[155,163] with varying effects possible depending on which control strategies are employed and whether pollutants are directly emitted into the atmosphere or formed in the atmosphere through chemistry. The likelihood and confidence statements are largely based on the second facet—because of well-documented inequalities in the distribution of other climate-sensitive environmental benefits and harms (KMs 9.2, 12.2, 15.2) and because of other forms of structural racism affecting the impacts of air pollution on health and well-being,[152,156] hence the *high confidence*. The cumulative burdens of air pollution with other climate change-driven hazards are *very likely* to increase in the coming decades in the absence of equity-focused emission controls. The author team assigns *high confidence* to the statement that equity-focused decision-making is critical for reducing air pollution inequities, as it has been borne out over decades of improved air quality across the US that air pollution disparities persist.[132,133,134,135,136,137] Sector, market, and pollutant threshold-based controls have been shown to have smaller equity benefits than location-specific interventions,[169] with California's GHG market serving as a real-world demonstration that GHG controls have the potential to worsen air pollution inequalities.[168]

Key Message 14.4

Climate Change Is Worsening Pollen Exposures and Adversely Impacting Health

Description of Evidence Base

This section was based on a review of the recent peer-reviewed literature. A large number of articles using new data and tools have been published in the past few years, and some have provided insight into the attribution of observed shifts in pollen metrics to anthropogenic climate change.

Recent developments have enhanced our understanding of climatic influences on pollen. These include improved understanding of plant phenology,[203,320,321,322,323] improved measurements of aeroallergen concentrations,[194,201,324] new modeling platforms for pollen emissions and transport,[204,205,207,325,326] novel analytics tools for recognizing pollen patterns,[327,328] automatic analysis of pollen types,[329,330] and remotely sensed data on meteorology, air quality, and phenology.[321,331,332] In addition to these methodological advances that allow for greater insight into factors influencing aeroallergen distribution and concentration, climatic influences are becoming clearer as the climate shifts further, and longer time series allow for greater confidence in the correlations observed.

Strategies for reducing the impact of allergic airway disease by avoiding and reducing pollen exposure,[213] which can be facilitated through public health campaigns[214] and taking medications to reduce immune response intensity,[212] have been established for years. More recent literature has highlighted gaps in diagnosing and treating allergic airway disease.[211]

Major Uncertainties and Research Gaps

There are several papers suggesting overall trends in pollen season and concentrations for total pollen and ragweed, but there is limited evidence for specific taxa, and there is less literature on climate change impacts on indoor and outdoor mold exposure. There is also limited evidence linking changes in health impacts with changes in exposure; however, there is abundant evidence that allergic respiratory disease is driven by exposure, so there is a strong presumption of a link. There is relatively limited information on the health equity impacts of changes in pollen exposure and on the effectiveness of early warning systems in reducing symptom burden. Lastly, there is little information quantifying the likelihood that investments in adaptation can fully close the adaptation gap and negate climate change–attributable shifts in allergic airway disease.

Description of Confidence and Likelihood

There is *very high confidence* in the linkage between aeroallergen exposure and the development and intermittent exacerbation of allergic airway disease and, by extension, that increased aeroallergen exposure damages the health of people who suffer from allergic airway disease.[185,186,187,188,189,190,192] There is *high confidence* and it is *very likely* that human-caused climate change, particularly warming, has already changed the patterns of pollen seasons based on both observational studies in North America as well as modeling studies assessing the influence of anthropogenic climate change compared against a counterfactual without anthropogenic climate forcing (Figure 14.6).[187,194,196,198,199,200,201] This evidence demonstrates that shifts in pollen concentrations vary by region. There is *high confidence* and it is *very likely* that as the climate changes further, these trends will continue and that further shifts in aeroallergen concentrations and distribution will depend on the rate at which the climate changes and, in particular, the rate of warming in a given location (Figure 14.6).[204,206,207,208,210] Based on past experience with managing allergic airway disease, there is *high confidence* that the health impacts associated with increased pollen from climate change can be counteracted fully or in part through improvements including increasing access to allergists, improved diagnosis and disease management, and allergy early warning systems.[211,212,213,214]

Key Message 14.5

Policies Can Reduce Greenhouse Gas Emissions and Improve Air Quality Simultaneously

Description of Evidence Base

The author team made use of the existing literature, emphasizing studies published since NCA4 but also referencing some classic papers published before 2018. The author team emphasizes here how decisions to control GHG emissions often have effects on air pollutant emissions. Similarly, decisions to control air pollutant emissions may influence GHG emissions. The author team therefore highlights the opportunity to control both types of emissions simultaneously through reductions in fossil fuels use, addressing both air pollution and climate change. Conclusions are informed by historical changes in emissions in the US and elsewhere, particularly the actions to implement air quality regulations through controls on smokestack emissions from power plants and large industries and controls on tailpipe emissions from motor vehicles. A fuller array of possible actions is presented in Figure 14.7, which emphasizes the capacity for actions to affect emissions of both air pollutants and GHGs in the near-term (targeting 2030), without explicit consideration for the cost-effectiveness of actions. Figure 14.7 does not present the potential for emissions reductions quantitatively, as the author team is not aware that this has been analyzed previously for the US. Rather the author team used information from several key sources to inform where boxes are placed in Figure 14.7, including US emissions inventories for GHGs[215] and air pollutants,[333] which constrain the potential reductions of some actions. Estimates of the global GHG mitigation capacity from the Sixth Assessment Report (AR6) of the Intergovernmental Panel on Climate Change (IPCC) Working Group III[221] help quantify the capacity for reduction, although these estimates are not specifically for the US, and estimates specifically for US energy system actions are from Figure 32.22. Estimates of sector contributions to US air pollution–related deaths[216] are also used, as are qualitative estimates of the effects of GHG reductions on air pollution in the United Kingdom.[65] Using these sources of information, emissions-reduction actions are put in order separately along the two axes in Figure 14.7 and then plotted. In some cases, minor changes in the order are made to fit the boxes on the figure. The boxes themselves are intended to communicate that there is some uncertainty in the emissions reductions, including boxes that straddle an axis, indicating uncertainty in the sign of the influence. Box positions should not be interpreted quantitatively (e.g., inferring that emissions-reduction capacity for one action is twice that of another action). Actions considered include those emphasized in past emissions reductions and considered for future action in the US, and not all possible actions can be included here. The analysis also focuses on technology actions rather than policy approaches (cap-and-trade, incentives for clean technology) used to achieve these goals.

There are many studies of the air quality and human health benefits due to the co-pollutant emission reductions from GHG mitigation actions.[226,227,228,229,230,231] The author team surveyed the literature and found 26 studies that either directly reported or contained enough information to quantify the monetary value of human health benefits from improved air quality per ton of mitigated GHG emissions. In some cases, it was necessary to contact the authors to ensure that the data were being interpreted correctly. These 26 studies form the basis of the range presented in the text ($8 to $430 in 2022 dollars, with a median of $100 per metric ton of CO_2). The estimates of human health benefits and costs from these studies span a range of two orders of magnitude because of different methods used, geographical scope, time periods analyzed, and GHG reduction actions considered. Figure 14.8 presents results from the subset of these studies that included both the air quality human health benefits and GHG mitigation costs. A complete list of the 26 studies and their reported values is available in the metadata for Figure 14.8.

Discussion of short-lived climate pollutants has a strong foundation in past research, as summarized in the IPCC AR6,[240] although some significant uncertainties remain in the magnitude of global anthropogenic radiative forcing for some of these species and in the net effects on climate from reductions of short-lived climate pollutants[252] in the United States in particular.

On the subject of social costs, since this chapter is about the link between climate change and air quality, it seemed appropriate to use costs that include both climate change and air pollution.[244] As the text states, "over half of [the value is] from ozone health impacts," so it is clear that this differs from commonly used costs, such as those produced by the US Government's Interagency Working Group on the Social Cost of Greenhouse Gases for use in regulations, which include only damages related to climate changes.[334]

Major Uncertainties and Research Gaps

Whereas there are new global modeling studies estimating air pollutant concentrations in future Shared Socioeconomic Pathway (SSP) scenarios, including the impacts of climate change on air quality, no study has yet downscaled these simulations to the United States for studying air pollution impacts. There is a gap in research that critically assesses how air pollution is projected to change in the US under scenarios that lead to decarbonization and approach net-zero emissions. There is also limited research in quantifying the effects of actions considered on both GHG and air pollutant emissions, as well as their costs and potential for emissions reductions, since much of the literature available focuses on GHG reductions without estimates of concurrent air pollutant emissions reductions.

Description of Confidence and Likelihood

There is *high confidence* and it is *very likely* that broad policies to reduce greenhouse gas emissions economy-wide in the United States will reduce air pollutant emissions and benefit air quality and health, although some individual actions may not achieve these benefits (Figure 14.7).[227,230,231] Many studies have estimated the air quality and human health benefits of greenhouse gas reduction actions, most of which have found that monetized benefits exceed the costs of greenhouse gas controls (see Figure 14.8 and associated metadata), when premature mortality is monetized using methods commonly used in the United States,[22] such as those used by the EPA. Therefore, there is *high confidence* that monetized health benefits would exceed costs for many greenhouse gas reduction actions, and it is *likely* that many specific actions will also have health benefits exceeding costs.[19,226,229] Based on several individual studies, there is *high confidence* that pursuing actions that emphasize reduced fossil fuel use, improved energy efficiency, and reductions in short-lived climate pollutants would not only put the United States on a trajectory that would substantially reduce GHG emissions and approach net-zero emissions (KM 32.4) but also substantially improve air quality and health.[224,231]

Introduction

Climate change has profound negative effects on human health. Climate-related extreme events that impact the US population include floods, droughts, wildfires, extreme temperatures, and storms. All are expected to increase in frequency, intensity, and extent (KM 2.2). Health risks from a changing climate include higher rates of heat-related morbidity and mortality; increases in the geographic range of some infectious diseases; greater exposure to poor air quality; increases in some adverse pregnancy outcomes; higher rates of pulmonary, neurological, and cardiovascular diseases; and worsening mental health.[1,2,3,4,5,6,7] These risks affect all US residents but have disproportionate repercussions for under-resourced and overburdened communities and individuals, such as pregnant people, communities of color, children, people with disabilities, people experiencing homelessness, people with chronic diseases, and older adults. Structural racism and discrimination against groups that have been marginalized play a direct role in health inequities and are public health crises.[8] Existing and projected human health impacts of climate change affect populations that are already experiencing an unprecedented decline in life expectancy due to environmental, social, political, and economic conditions that determine community health and well-being.[9,10,11] Creating climate-resilient health systems, implementing adaptation measures, and mitigating greenhouse gas (GHG) emissions can protect human health.

Key Message 15.1

Climate Change Is Harming Human Health

It is an established fact that climate change is harming physical, mental, spiritual, and community health and well-being through the increasing frequency and intensity of extreme events, increasing cases of infectious and vector-borne diseases, and declines in food and water quality and security. Climate-related hazards will continue to grow, increasing morbidity and mortality across all regions of the US (*very likely, very high confidence*).

Extreme Heat

In recent decades, rising temperatures have increased heat-related health impacts in the US (Figures 21.8, 22.9, 25.3, 26.2, 27.8, 28.7; KM 2.2).[12] Higher temperatures are associated with adverse pregnancy and birth outcomes, mental health impacts, and increased emergency room visits and hospitalizations related to cardiovascular disease, diabetes, electrolyte imbalance, renal failure, and respiratory outcomes.[13,14,15] Heat-related health impacts are greatest among children, adults over age 65, those with disabilities, people with mental health or substance-use disorders; and those who are pregnant, lack access to cooling, or engage in outdoor labor and activities (Figure 15.1).[13,16,17,18,19] Black, Latinx, Asian, historically redlined, and urban communities are disproportionately exposed to heat, as are those with low wealth and people experiencing homelessness (Figures 12.4, 12.6; KM 22.2);[20,21,22] these groups also report being more worried about heat risks.[23,24,25] Certain medications for management of cardiovascular conditions and mental health disorders may accentuate heat-health risk.[26,27] Heat-related death and illness will continue to increase unless climate change adaptation and mitigation policies are implemented (KM 15.3).[28,29]

Heat and Health Equity

Heat does not impact all communities equally.

Figure 15.1. While anyone can be impacted by heat, location, economics, compound risks, and social and racial factors influence who is most at risk. These impacts disproportionately affect BIPOC (Black, Indigenous, and People of Color) communities as well as communities with low wealth. Figure credit: CDC, University of Colorado, NOAA NCEI, and CISESS NC. Drought

Among weather and climate disasters in the US over the last 40 years that have caused more than a billion dollars of economic loss, drought is responsible for the second-highest number of climate-related deaths—approximately 99 per year (Figure A4.9).[30] However, these statistics probably underreport the total number of deaths, as these estimates account only for heat-related mortality that accompanies droughts.[31] There is growing evidence of an association between drought and increased mortality in adults ages 25–64 in both rural and urban populations.[32,33] Drought can worsen air quality, resulting in adverse health outcomes such as increased cardiovascular and pulmonary disease and premature death (KM 4.2).[34,35] It can also decrease water quantity and quality, which can cause increased exposure to heavy metals, bacteria, and other harmful contaminants (KMs 30.2, 30.2).[36,37,38] Because farmers rely on the land for their livelihood, drought during the growing season is associated with worsening mental health among rural US farmers (KMs 11.2, 22.4).[39]

Wildfires

Wildfire activity has significantly increased over the last few decades, especially in the western US (KM 14.2; Figure 28.9; Focus on Western Wildfires). Roughly half of the increase in burned areas in the US can be attributed to a warming climate.[40] Wildfires and resulting poor air quality can cause disruptions to a person's life, including loss of livelihood and displacement, and can lead to multiple adverse health effects, including death, illnesses, injuries, adverse reproductive outcomes, poor mental health consequences, and declines in

psychosocial well-being.[41,42,43,44] Exposure to smoke from wildfires is associated with emergency department visits, hospitalizations, and deaths.[45,46,47,48,49]

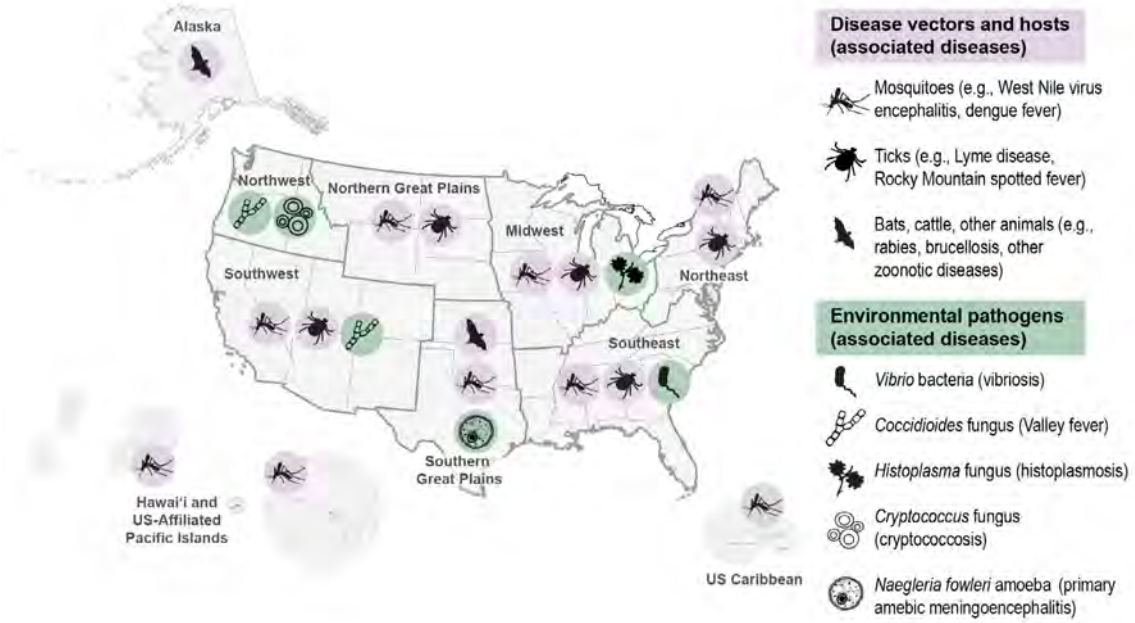
Infectious Diseases

Climate change is expected to alter the distribution, abundance, and seasonality of pathogens and their associated infections (Figure 15.2; Focus on COVID-19 and Climate Change).[50,51,52,53] The range of vampire bats in Texas and Florida is expected to increase due to rising temperatures, which can lead to increased human rabies exposure.[54,55] Exposure to rabies and other zoonoses like brucellosis and toxoplasmosis is also of increasing concern in Alaska, especially for residents who practice subsistence hunting and gathering (KM 29.1).[56] In the eastern US, exposure to the amoeba (*Naegleria fowleri*) that causes primary amebic meningoencephalitis has been documented farther north.[57] Environmental fungal diseases like blastomycosis, coccidioidomycosis (Valley fever), cryptococcosis, and histoplasmosis are expected to be impacted by climate change.[58,59,60] Valley fever is expected to spread northward as drought and temperatures increase (KM 28.4). Case numbers are projected to increase by 220% by the end of the century under a very high scenario (RCP8.5).[61] Valley fever tends to afflict construction and agricultural workers,[62,63,64] and the disease disproportionately impacts Black and Latinx populations, possibly due to occupational exposure.[65,66,67,68]

Lyme disease and other tick-borne diseases account for approximately 80% of all reported cases of vector-borne diseases in the US[69,70] and have steadily increased over the last 20 years due to multiple factors, including climate change (Figure 24.8).[71,72,73] Increased distribution and abundance of ticks are projected to increase human disease cases.[74,75,76,77,78,79] Climate change has contributed to the expansion over the last 20–30 years of the Lone Star tick[80,81,82,83,84] and the Gulf Coast tick, which transmit multiple pathogens.[85] Climate change extends ticks' seasonal activity, prolonging human exposure.[76,86,87,88,89]

Mosquito-borne pathogen spread is influenced by weather, climate, and social factors.[90,91,92] Climate change alters the diversity and distribution of mosquito vectors of dengue, Zika, and chikungunya viruses.[93,94,95,96,97] Dengue is currently a risk in the contiguous US, the US Caribbean, Hawai'i, and US-affiliated Pacific Islands (KMs 23.1, 30.2).[98,99] Increasing weather variability (KM 4.1) may increase West Nile virus transmission. Regional West Nile virus projections indicate geographic expansion in the Northeast over the next 50 years due to climate-related changes in mosquito population distribution (KMs 22.2, 24.3).[100,101,102] Mosquito-borne transmission of other encephalitis viruses has been sporadic in the last decade and may increase as climate change extends seasonality and expands habitat suitability for mosquito species.[103,104,105,106,107,108,109,110,111]

Regional Examples of Climate-Sensitive Infectious Diseases



Some climate-sensitive infectious diseases are expected to see expanded geographic range and extended seasonality.

Figure 15.2. The map shows select examples of regional climate-sensitive infectious diseases, based on recent changes in geographic range or incidence. Some regions will experience increases in tick- and mosquito-borne diseases, zoonotic diseases, and pathogens, both in geographic area and extended seasonality. Figure credit: Los Alamos National Laboratory, CDC, Columbia University, University of Arizona, and University of Colorado.

Food and Water

Climate change negatively impacts water quality, water security, food security, and nutrition, which harms health, particularly for communities that rely on agriculture, fishing, and subsistence lifestyles (KMs 4.1, 11.2, 22.2, 23.1, 25.3). For example, the 2021 Pacific Northwest heatwave affected the livelihoods of farmers and Tribes by damaging crops and causing a die-off of mussels, clams, and oysters.[112]

The incidence of certain diseases caused by foodborne and waterborne pathogens is expected to increase due to climate conditions that promote bacterial growth and geographic spread. For instance, vibriosis is a disease caused by ingesting *Vibrio* bacteria in contaminated shellfish or water sources. Symptoms range from food poisoning–like illness to death. Climate change–related vibriosis cases are projected to increase by 51% by 2090 under an intermediate scenario (RCP4.5)[113] due to increasing *Vibrio* populations in warming waters, changing salinity, sea level rise–related coastal changes, and flooding (KM 9.1).[113,114,115,116,117]

Mental and Spiritual Health

Extreme weather events, wildfires, and slow-onset disasters (e.g., drought, sea level rise) can contribute to adverse mental and spiritual health outcomes. These harms may arise from forced displacement and migration (KM 20.3), trauma, loss of sense of place and belonging, and disruption of livelihoods, lifeways, and social support systems.[118] Under-resourced communities bear greater mental and spiritual health burdens (KMs 22.2, 25.2, 27.5).

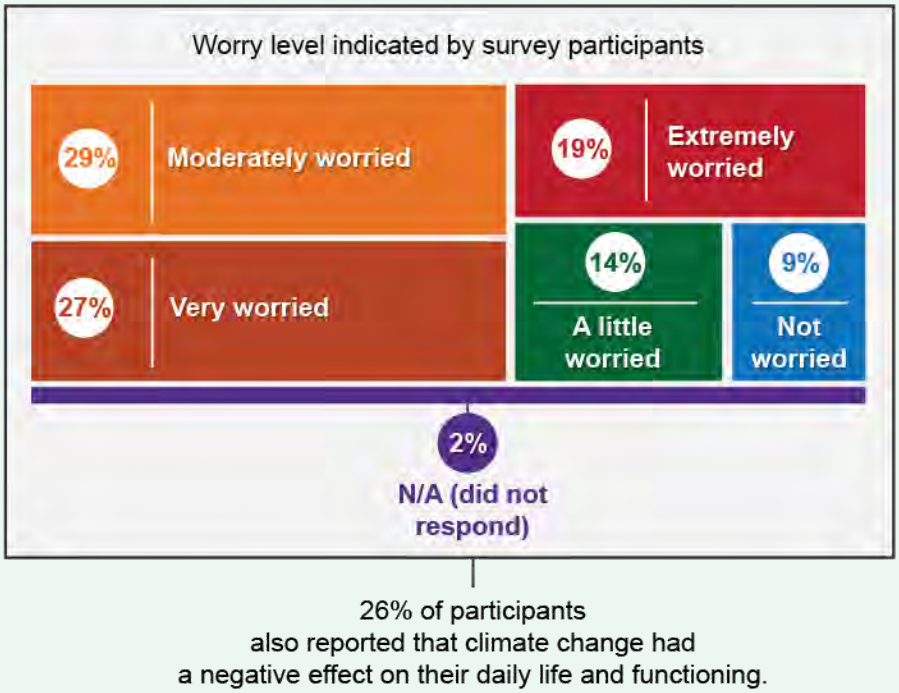
Mental health conditions including anxiety, depression, and suicide have become more prevalent in the US in the past decade, especially among adolescents.[119,120] Climate change may increase these mental health burdens.[55] Greater need for mental health services and psychiatric medications, as well as higher rates of anxiety, have been reported following major hurricanes (KM 23.1). For example, one in six mothers with low income experienced continued post-traumatic stress symptoms 12 years after Hurricane Katrina.[121,122,123,124] Many survivors of California's deadliest wildfire, the 2018 Camp Fire, experienced post-traumatic stress, depression, and anxiety[42] related to home loss and community disruption. Extreme heat exposure has been linked to worsening mental health, including suicide and interpersonal violence.[7,125]

Degradation or destruction of culturally significant places and flora and fauna relatives (KM 24.2),[126,127] shifts in timing of ceremonial practices, disruption of intergenerational teachings and sharing of knowledge and wisdom, and loss of place-based spirituality and traditional livelihoods and lifeways put spiritual health at risk, especially for Indigenous communities.[128,129]

Box 15.1. Child and Adolescent Mental Health

Compared to previous generations, US children born in 2020 are more likely to experience climate-related adverse childhood events (ACEs) from damage to their homes, schools, and communities.[130] Children with four or more ACEs have 3- to 6-fold greater odds of having anxiety, depression, and substance use disorders and 30-fold greater odds of attempting suicide, in addition to greater physical health risks.[131] Concerns about a potentially uninhabitable world due to climate change can result in "eco-anxiety." Nearly 60% of 1,000 surveyed US adolescents reported anxiety about climate change, and nearly half believe that "humanity is doomed" (Figure 15.3),[132] despite evidence to the contrary (Chs. 1, 2, 31, 32). Psychological resilience training along with mental health care may lessen anxiety and promote engagement on climate change.[5,7,133,134] Youth climate education programs have focused on empowerment with the intent to reframe threats from climate change as opportunities to pursue solutions.[135,136]

Children's Mental Health



Out of 1,000 children and young people surveyed in the US, a majority expressed worry about climate change impacts to people and the planet.

Figure 15.3. The figure shows the level of worry about climate change among young people ages 16–25. In the US, 46% of respondents said they were "very" or "extremely" worried about climate change, and 26% of respondents indicated that their feelings about climate change negatively affected their daily life and functioning, including at least one of the following: eating, concentrating, work, school, sleeping, spending time in nature, playing, having fun, and relationships.[132] Figure credit: Boston Children's Hospital, NOAA NCEI, and CISESS NC.

Compounding and Cascading Hazards

Multiple climate-related extreme events that occur concurrently or in rapid succession (KM 2.3; Focus on Compound Events) can result in greater health impacts than singular events and limit the ability of individuals and communities to effectively prepare for, manage, and recover from these events. A singular event that cascades across multiple sectors or regions can result in compounded adverse health consequences. Examples include back-to-back heatwaves, heatwaves during wildfires, drinking-water contamination after flooding, and vector-control program breakdowns during and after flooding.[137] During 2005–2013, windstorms combined with power outages increased emergency department visits, hospital stays, and injury costs in New York, particularly for older individuals and Medicaid recipients.[138]

Occupational Safety and Health Impacts

Climate-related increases in temperature are associated with increases in occupational injuries and occupational exposure to heat, potentially resulting in illness or death (KM 11.2).[139,140,141] Between 2011 and 2019, an average of 3,500 heat-related injuries, resulting in 38 fatalities per year, were reported to OSHA.[139] Between 2001 and 2018, higher-temperature days in California were associated with greatest increased risk of occupational injuries to men, lower-income workers, and young workers. Repeated heat stress coupled with dehydration in occupational environments is a risk factor for the development of kidney disease.[142] Extreme heat is expected to lead to lost labor hours, particularly for workers of color, individuals with low income, and those without a high school diploma. Additionally, these groups are more likely to live in areas where labor is most impacted by extreme heat.[143] Projected estimates of annual lost wages due to unsafe heat range from $19.2 billion to $46 billion (in 2022 dollars) by midcentury (under an intermediate scenario, RCP4.5).[144,145] Industries where workers experience increased risk of heat-related mortality include agriculture (KM 11.2), construction, transportation and warehousing, and waste management.[139] Workers can also face unsafe heat in indoor environments not equipped with adequate climate control.[139] Worker safety is also affected by climate change impacts on economic opportunity and wealth (KM 19.3), exposure to infectious diseases (Focus on COVID-19 and Climate Change), extreme events (Focus on Western Wildfires), and increased mental health risks.[146]

Key Message 15.2

Systemic Racism and Discrimination Exacerbate Climate Impacts on Human Health

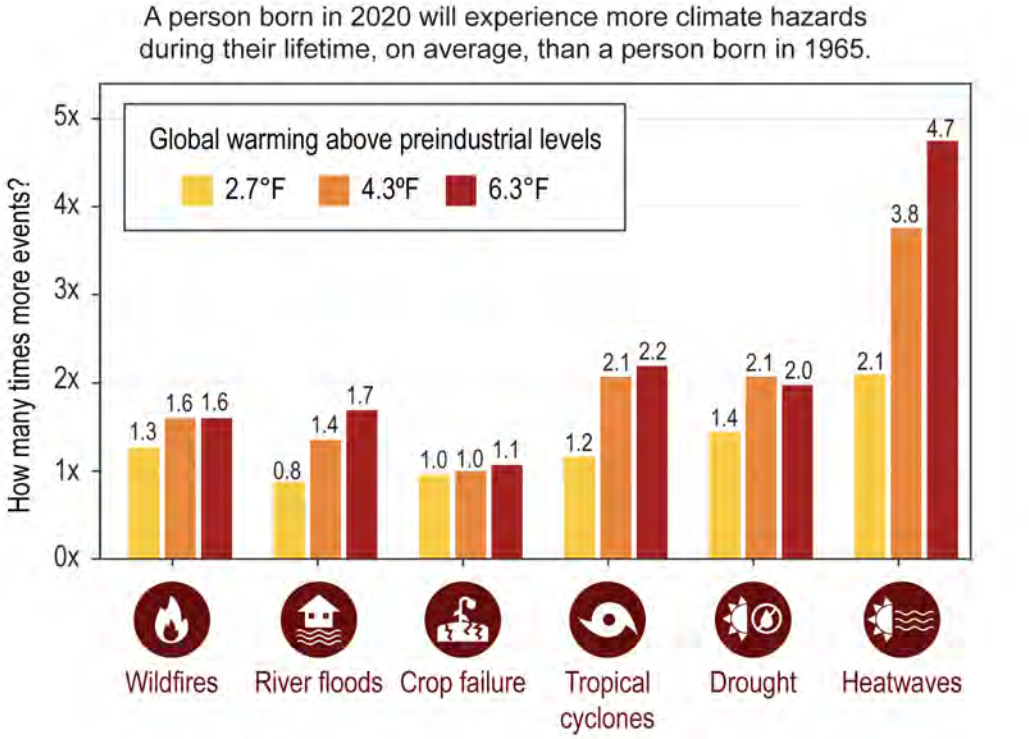
Climate change unequivocally worsens physical, mental, spiritual, and community health and well-being, as well as social inequities. It is an established fact that climate-related impacts disproportionately harm communities and people who have been marginalized. These include BIPOC (Black, Indigenous, and People of Color), individuals and communities with low wealth, women, people with disabilities or chronic diseases, sexual and gender minorities, and children.

Community Health and Health Equity

Climate hazards negatively impact physical, mental, and community health.[147] Although extreme weather threatens all communities (Figure 15.3), health-related burdens are experienced more acutely by BIPOC and low-wealth communities that have been under-resourced and overburdened (KM 19.1; Figure 19.2).[143,148,149] Climate change creates intergenerational inequities as younger generations must endure more extreme

weather events than older ones (Figure 15.4). Valuation of intergenerational inequity can inform resilience and mitigation investments. Climate change is a threat multiplier, interacting with and magnifying other life-threatening stressors (Figure 15.5).[150] Fenceline communities—those located adjacent to hazardous industrial facilities, which are disproportionately BIPOC and low-wealth—face higher risks from chemical and industrial disasters following extreme weather.[151,152,153,154,155,156,157,158,159,160,161,162] Hazardous sites, threatened by flooding and sea level rise, exacerbate climate-related health inequities to BIPOC and communities with low wealth (KM 9.2).[163] Additionally, about 70% of Superfund sites—locations contaminated by hazardous materials designated for clean-up—are located within one mile of federally assisted housing, which disproportionately houses people of color, individuals with low wealth, and those with disabilities.[164]

Intergenerational Inequity



The number of climate hazards a person born in North America will experience during their lifetime depends on how much Earth warms above preindustrial levels.

Figure 15.4. People born in North America in 2020, on average, will be exposed to more climate-related hazards compared to people born in 1965, an indication of intergenerational inequity. Figure credit: Boston Children's Hospital, NOAA NCEI, and CISESS NC.

Food and Water Systems

Disruptions to food and water quality pose challenges to human health and disproportionately affect BIPOC communities, households with low wealth, single-parent households, and children (KM 11.2; Box 23.1).[165,166] In 2020, 10.5% of US households were food insecure, with higher rates reported among populations that have been marginalized.[165] There are growing concerns about aging or inadequate water infrastructure,[167] especially among households, including many in the Navajo Nation, who experience unequal access to piped and treated drinking water and who are dependent on hauling large quantities of water from nearby facilities.[168] Chemical, physical, and microbial contaminants (e.g., algal blooms and the toxins that cause

paralytic shellfish poisoning) threaten water supplies under drought conditions and high temperatures (KM 22.2), which is of particular concern among Indigenous populations who rely on subsistence fishing (KMs 10.1, 28.1, 29.1).

Healthcare Access and Delivery

Climate-related extreme events have resulted in reductions in healthcare access and an increase in illness and death that can extend for months after the acute event, especially for communities with low wealth (KM 23.1).[169,170] Extreme events can disrupt care for chronic physical and mental health conditions. After hurricanes, risk of death among patients with lung cancer rises in proportion to the length of disaster declarations,[171] and delays in access to dialysis after Hurricane Sandy were associated with more emergency department visits and mortality among patients with chronic kidney disease.[172] Infrastructure and transportation failures contribute to poor health outcomes due to closures, lack of electricity or clean water sources, and/or road failures that prevent access to healthcare providers.[173]

Tribal and Indigenous Peoples' Health

Tribal and Indigenous Peoples are disproportionately impacted by climate change, and they often equate the health of their people, culture, and traditional practices to the health of the environment (KMs 16.1, 29.1, 27.5, 30.2).[127,174,175] In addition to enduring the historical injustices of colonization, forced relocation, and land dispossession,[176] Indigenous Peoples are among the first to face the spiritual, physical, and mental health threats and impacts of climate change. This undermines their ability to maintain and access their cultural and economic lifeways and worsens community-wide vulnerabilities, such as limited water availability for use by humans, animals, and plants (KM 16.1).[129] Climate-related hazards such as flooding, erosion, sea level rise, and melting ice may lead to impassable roads in remote parts of Tribal territories, thereby widening gaps in the ability to access adequate healthcare (KM 29.2; Focus on Risks to Supply Chains).[177]

Persons with Disabilities' Health

Climate change disproportionately and differentially harms the health of persons with disabilities, magnifies existing health and socioeconomic inequalities, creates unique challenges, and compounds disparities due to multiple discrimination.[178] During climate disasters, persons with disabilities are at heightened risk of mortality and injury, and they experience disruptions accessing assistive devices, medication, dialysis, other health services, and social support.[178,179] During periods of higher ambient temperatures and heatwaves, persons with physical and mental disabilities experience adverse health impacts, increased emergency room visits, and higher rates of mortality; cooling measures may be physically or financially inaccessible.[178,180] Persons with disabilities are also at elevated risk of exposure to chronic air pollution, as they disproportionately live in neighborhoods with heightened exposure to fine particulate matter due to lower wealth, higher unemployment, and undereducation relative to nondisabled peers.[181]

African American and Latinx Peoples' Health

Climate change has had and will continue to have disproportionate adverse health impacts on communities with low wealth and BIPOC communities, worsening already-existing health disparities. Discriminatory policies and practices in housing, education, and siting of polluting facilities, including disinvestment in infrastructure and healthcare, amplify adverse climate-related health impacts (KM 22.2; Focus on Risks to Supply Chains).[150] Latinx populations, compared to other demographic groups, are 43% more likely to live in areas that will experience the highest labor reduction hours due to extreme high temperatures (with 2°C (3.6°F) of global warming by 2085–2095 compared to the 1986–2005 reference period).[143,145] African Americans are also expected to face disproportionately greater risks from climate change. African Americans and individuals with low income face higher risks of death from climate-driven floods and

air pollution compared to White people (Box 4.2).[143] People of color are disproportionately exposed to greenhouse gas co-pollutants like small particulate matter and face adverse health impacts as a result.[182,183] Due to housing discrimination and redlining, African Americans are more likely to live in neighborhoods with fewer trees and more pavement, suffer disproportionately from heat-related deaths, be exposed to worse air quality, and experience higher rates of asthma-related emergency room visits (KM 22.2; Figures 12.4, 12.6),[184,185,186,187] all of which are compounded by climate change. Latinx and other BIPOC communities face similar challenges (KM 14.3).[188,189]

Women's Health

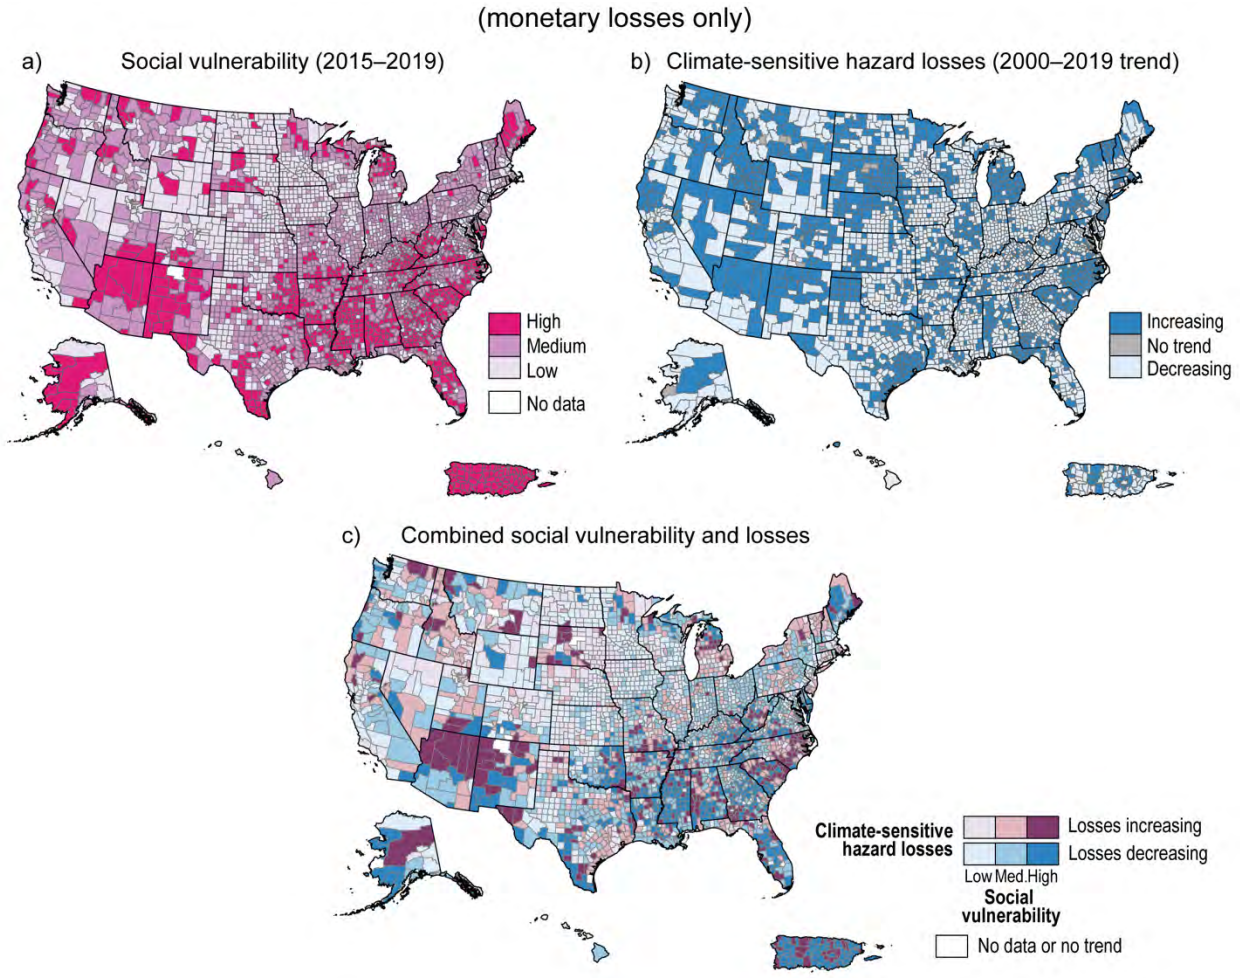
Women disproportionately experience the burden of climate change because of unique mental, sexual, and reproductive health needs that intersect with existing social, racial, and economic disparities. Women, and particularly women of color, are more likely to live in communities with low wealth,[190,191] which is associated with food insecurity[192] and exposure to particulate matter, extreme heat,[2] and climate-related disasters.[193,194] Pregnant cisgender women are particularly vulnerable because exposure to heat, particulate matter, and disaster-associated stressors leads to poor pregnancy outcomes, including miscarriages and low birth weight.[1,195] These factors contribute to maternal mortality, which is more prevalent in the US than in any other developed nation.[196] These outcomes are more likely in groups that have been marginalized, particularly Black pregnant people,[197,198] exacerbating existing social inequities.

In utero exposure to maternal stress during climate-related disasters is linked to subsequent psychiatric disorders in early childhood.[199] Additionally, women have higher caregiving burdens and decreased healthcare access, which makes recovering from climate-driven exposures more difficult. Transgender women may be required to stay in male-only shelters during climate-related disasters, negatively impacting their mental and physical health.[200,201]

Sexual and Gender Minorities' Health

Sexual and gender minorities (SGMs) face social, economic, and health disparities and, as a result, experience greater risk of harm from climate change. SGMs are found in all populations, including frontline communities, and can experience compounding disparities and impacts on the basis of sexual orientation and gender identity. In 2015, Black and Latinx transgender individuals were more than three times as likely as the overall US population to be living below the poverty line (KMs 19.1, 23.1).[190] Indigenous SGMs face heightened health disparities as climate change continues to impact lifeways and economies.[202] SGMs may lack access to critical services during extreme events and are often not included in disaster preparedness and response plans due to discrimination and institutional structures that prioritize the needs of cisgender, heterosexual individuals;[200] may not recognize "chosen families"; and increasingly rely on faith-based organizations as first responders during disasters, which in some cases have blamed SGMs for devastating hurricanes and wildfires as a punishment from God.[193] These discriminatory beliefs have led some SGMs to not seek services at faith-based organizations for fear of being turned away or their SGM status being outed.[203] Because of religious bias, healthcare workers may also refuse to provide health services to or discriminate against SGMs during disasters.[204]

Social Vulnerability and Climate Hazards



Some highly vulnerable areas also have high economic losses from climate hazards.

Figure 15.5. Panel (**a**) maps counties based on their Social Vulnerability Index (SoVI) scores for the period 2015–2019. SoVI uses 29 different inputs that characterize underlying socioeconomic and demographic factors, and the index is classified (high, medium, low) using standard deviations. Panel (**b**) shows counties with an increasing trend in climate-sensitive hazard losses (2000–2019) based on data from the Arizona State University/ASU Spatial Hazard Events and Losses Database for the US (SHELDUS). The data is based on property losses and excludes injuries and fatalities from climate-sensitive hazard losses. Exclusion of fatality (especially from heat) explains why some areas of the Southwest appear to have a seemingly decreasing loss trend. The composite map (**c**) identifies counties with high social vulnerability that have less capacity to prepare for, respond to, and rebound from increasing climate-related losses. SoVI does not fully capture the disproportionate impacts of climate hazards in specific neighborhoods, populations, and cultural groups within a county, nor does it account for risk created by historic marginalization. Key Message 15.3

Timely, Effective, and Culturally Appropriate Adaptation and Mitigation Actions Protect Human Health

In every sector of society, implementing timely, effective, and culturally appropriate adaptation measures (*high confidence*), creating climate-resilient health systems (*high confidence*), and preventing the release of greenhouse gases can protect human health and improve health equity (*high confidence*).

Risk Management and Integrated Approaches

Proactive and continuous risk management to protect at-risk groups and healthcare facilities is critical to human health and well-being (KM 31.3). This includes integrated approaches that mainstream health into food systems (KM 11.1), infrastructure, water, and sanitation policies. Mitigation options with significant health benefits include reducing point-source (e.g., coal-fired power plants) and mobile-source emissions, increasing active transport (e.g., walking), and increasing consumption of vegetables, legumes, fruits, and nuts (KMs 13.3, 32.4).[205] The economic value of avoided hospitalizations and premature deaths from mitigation activities is larger than the cost of implementation.[29]

Climate-Resilient and Sustainable Health Systems

A climate-resilient health system can "anticipate, respond to, cope with, recover from, and adapt to" climate change to improve the health of communities (KMs 18.2, 19.2).[206,207] Focusing on equity, proactively addressing mental health needs, and linking to community health resources such as community health workers and long-term support and services can create a climate-resilient health system. Climate-related hazards routinely stress and disrupt healthcare systems and threaten access to healthcare for many. For example, a flooding event in 2019 damaged hospitals and disrupted access to healthcare across the central US.[208] Many hospitals (9.3%), nursing homes (10.2%), and pharmacies (12.1%) are at risk of flooding.[209] The COVID-19 pandemic exposed the lack of resilience of the healthcare system when confronted with a large, prolonged increase in healthcare needs (Focus on COVID-19 and Climate Change). Climate-sensitive health problems are linked to a significant economic burden on the healthcare system. There are numerous tools to identify threats and vulnerabilities to healthcare systems—such as the US Department of Health and Human Services' Sustainable and Climate Resilient Health Care Facilities Initiative—with frameworks to guide planning and implementation.[210]

Healthcare systems can play an important role in GHG reduction. The healthcare sector is responsible for 8.5% of US GHG emissions (Figure 19.5).[211,212] Transitioning to clean energy sources and introducing sustainable technologies into healthcare systems would reduce these emissions and associated health harms (KM 32.4).

Benefits of Reducing Air Pollution

Air pollution is a leading cause of premature death worldwide (KM 14.1).[213] It has substantial impacts on lung, heart, and brain health; cancer; and mental health.[214] Reducing GHG emissions and human-caused air pollution would save lives and decrease the burden on the healthcare system (KMs 14.5, 32.4; Figure 32.15).

Disease Surveillance

Implementing surveillance programs for climate-sensitive infectious diseases and non-infectious health outcomes (e.g., heat stroke, respiratory disease, mental and behavior health indicators) is an important

adaptation measure. The COVID-19 pandemic illustrated the need for modernization of the US surveillance system and the role of innovative surveillance strategies such as wastewater testing and community-based participatory surveillance (Focus on COVID-19 and Climate Change). Monitoring disease case counts, corresponding indicators (animal health and vector populations), and health outcomes facilitates identifying seasonal trends, responses to climate and environmental variability, geographic hotspots for diseases, and new or reemerging threats.[65,215,216] Enhanced disease surveillance identifies populations most at risk for contracting a disease and improves health by raising disease awareness and reducing time to diagnosis and treatment.[217] This increases capacity to plan for and prevent disease spread or outbreaks, such as by creating predictive models of disease transmission, implementing vector abatement programs, and developing and stockpiling vaccines and pharmaceuticals.[101,218,219,220]

Extreme Heat

Increasing temperatures, urbanization, and an aging population (KM 2.2)[221,222] can result in increased heat-related deaths (KM 2.2).[221,222] Limiting warming to 1.5°C (2.7°F) above preindustrial levels (compared to 3°C, or 5.4°F) and timely adaptations could substantially decrease heat-related deaths, especially in cities.[223,224,225,226] Adaptations range from ensuring equitable access to cool spaces and reducing social isolation to augmenting heat warning systems and improving green infrastructure (KMs 12.3, 12.4).[224]

Air-conditioning access is limited for unhoused populations and households with low wealth. High electricity costs prevent effective use of air-conditioning.[227] Poor self-reported health and reduced life expectancy are more prevalent where families spend a large proportion of household income on residential energy.[228] Government programs can help families reduce their energy costs.[229] Home weatherization can improve health conditions and reduce healthcare costs while reducing GHG emissions, providing societal benefits greater than the implementation cost (KM 5.3).[230,231] There are self-reported health benefits from energy retrofits in households with low wealth.[232]

Increased air-conditioning use can exacerbate the urban heat island effect by transferring hot air from buildings to the outdoor environment (Ch. 12; Figure 12.4) and can increase electricity-related emissions of GHGs and other air pollutants.[233] Buildings that rely on air-conditioning may become dangerously hot during prolonged power outages.[234,235,236,237,238] Sustainable cooling strategies are in development, such as energy-efficient systems (e.g., heat pumps and fans) and affordable passive cooling (e.g., night-flush ventilation).[239,240,241,242]

Wildfires

Under a range of future climate scenarios, wildfire pollutant emissions are expected to increase and result in significant health burdens.[243] Integrated wildfire management and adaptation strategies are critical to reducing deaths and illnesses, as wildfire risk cannot be eliminated. Proactive and effective management of fuel loads (e.g., through prescribed and cultural burning) can reduce wildfire size and intensity, but there may be unintended health consequences.[244] Strategies to reduce wildland fire smoke exposure include personal actions and community-level interventions (KM 14.2).[245] Early warning systems identify areas and populations experiencing higher smoke exposure on a near-real-time basis.[246,247]

Vector-Borne Diseases

Climate change is a significant contributing factor to the increase in vector-borne disease cases reported over the last 20 years.[71,72,73] To adapt to these changing risks, new technologies to prevent transmission of vector-borne diseases are urgently needed, as traditional control measures, including insecticides, are rapidly becoming ineffective.[71,248,249,250] Recent advances include vaccines, spatial repellents, genetically

modified mosquitoes, and *Wolbachia* (a naturally occurring bacteria that reduces transmission of viruses such as dengue).

However, these novel adaptations are not yet operational due to funding, regulatory status, and infrastructure needs. Buy-in from communities and decision-makers is critical to ensure that emerging strategies can be utilized to protect health.[92,218,251,252,253,254] Coupling novel strategies with well-established community engagement practices, such as remediating vector habitat and increasing personal protective measures, can effectively reduce risk and empower communities.[255,256]

Mental and Spiritual Health

Actions to support community social cohesion and cultural continuance, establish trusted and effective communication systems, and ensure that community members and/or officials can effectively manage disasters may buffer against adverse mental health outcomes.[147] A personal sense of agency to take climate action can reduce adverse mental health outcomes during extreme events. It can provide hope for survival and contribute to greater participation in community responses to climate change, which may also improve mental health resilience.[257]

Community-Level Resilience and Adaptation Strategies to Build Capacity

Communities, connected through relationships and practices,[258] have unique priorities, traditions, and histories relevant to adaptation.[259] Many communities are already making proactive intergenerational adaptation decisions to reduce exposure to climate impacts, build capacity, and enhance healing and self-determination in the face of historical traumas (Figure 15.6).[260] Many Indigenous Peoples in the US practice cultural burning, a fire management approach that promotes ecosystem resilience and growth of culturally important medicinal plants[129,261] while also serving as an eco-centric adaptation strategy for improved planetary health.[262,263] The Swinomish Indian Tribal Community used values-driven data and community input in developing Indigenous health indicators and a climate change health assessment for adaptation decision-making; the indicators included community connection, self-determination, education, resilience, cultural use, and resource security.[174,264,265]

External adaptation strategies can exacerbate inequities through, for example, institutional racism, uneven distribution of adaptive capacity, and resource allocation that ignores distributive and historical injustices (KM 31.1). Adaptations (e.g., tree planting) that make an area more appealing for people with higher income could push existing residents out, resulting in eco-gentrification.[266,267] There are policies and institutional barriers to implementing whole-community adaptation actions.[129,268]

Indigenous-Led Disaster Recovery Actions and Improved Health Outcomes

Louisiana Tribal leaders are upholding sovereignty and self-determination in their climate adaptation actions following hurricane damage.

Figure 15.6. Tribal leaders from coastal Louisiana shared Indigenous and local knowledge, wisdom, and experiences of the health impacts and resilience-building recovery actions following Hurricane Ida, which made landfall in coastal Louisiana in August 2021. Interviews were recorded during a convening where the Tribal leaders came together to share how Louisiana Tribes are adapting to climate change while upholding sovereignty and working to improve health outcomes. Link to videos. Image credit: ©Craig Richard and Unitarian Universalist Service Committee, in collaboration with the First People's Conservation Council of Louisiana, Lowlander Center, Livelihoods Knowledge Exchange Network, and Disaster Justice Network, July 2022.

Addressing immediate needs and developing healthier long-term outcomes that reduce inequities[269] and strengthen community resilience[147] involves collaboration and cooperation across multiple scales. Persons with disabilities, for example, are often excluded from adaptation and mitigation efforts,[270] and there is a strong need for disability-inclusive climate planning and response.[271] The most impacted communities must be included in decision-making, from visioning and planning through implementation.[258,272,273]

Community adaptation capacity is enhanced by building and sharing flexibility, humanity, spirituality, and resilience. To be effective, adaptation strategies must integrate workforce development into co-governance and promote institutional support systems for community-defined, -driven, and -led adaptation efforts that include a diversity of cultures, histories, lifeways, and knowledge systems.[129,260,274]

Traceable Accounts

Process Description

Chapter authors were selected over a three-week period in August 2021. The initial discussion centered around authors who had been nominated or who had self-nominated. The chapter lead author and federal coordinating lead author then expanded the list and focused on balancing career stage, topic expertise, geographic location, and type of institution (academic, federal government, nonprofit). Once the chapter lead author had narrowed down the search, the authors were contacted. All contacted authors agreed to participate and were invited to complete the survey to be officially enrolled. The 18 authors for the Human Health chapter are subject experts in the topics selected for inclusion. Technical contributors were added as needed during the response to comments from the public and the National Academies to bring in additional data and subject-matter expertise.

Authors reviewed and evaluated scientific literature on the human health impacts of climate change, with a focus on new and emerging evidence since the Fourth National Climate Assessment (NCA4). Authors also reviewed technical inputs (submitted as part of the NCA5 process) for relevant information. The entire author team regularly met virtually to create and review chapter content; all authors participated in determining Key Messages and chapter topics and content. A public engagement workshop was held to solicit public input. The chapter was informed by workshop participants' concerns and comments. Authors also met in person in April 2023 to continue writing and incorporating additional information in response to review comments.

Key Message 15.1

Climate Change Is Harming Human Health

Description of Evidence Base

Multiple lines of evidence demonstrate that climate change is already harming human health.[69,269,275,276] Evidence indicates that extreme events and climate-related environmental changes will continue to place stress on food, water, and energy supplies (KM 2.2). This, in turn, will negatively impact the health of the US population in many ways, including reduced access to healthcare. Based on recent peer-reviewed research, this Key Message outlined the existing health impacts in the areas of extreme heat, drought, wildfires, infectious diseases, food and water quality and security, mental and spiritual health, compounding hazards, and occupational safety. Studies demonstrate that these trends will continue to increase.[269,277]

Evolving attribution science allows researchers to study how extreme events, and resultant health impacts, were influenced by climate change. This growing evidence line contributes to our understanding of the role of climate change in the health impacts of heatwaves, floods, droughts, and other disasters.[278,279,280,281]

Major Uncertainties and Research Gaps

While ample evidence demonstrates the health impacts of climate change, uncertainties remain on specific aspects of these impacts. For example, uncertainties in projections of human health outcomes in response to climate change can partially stem from the underlying human case data involved in the research, which is subject to underreporting or underdiagnosing the human case counts. Quantifying the impacts of climate change on human health is challenging due to lack of long-term surveillance and datasets; differential exposures based on location; and underlying health inequities.[282] In addition, health surveillance related to extreme weather is being improved through utilization of syndromic ("real-time") surveillance, data mod-

ernization initiatives, and integration of existing surveillance systems. Decades of research on the impacts of climate change on infectious disease illustrate the complexity of the pathways by which climate change may alter disease transmission dynamics. Uncertainties arise from geographic differences in social–behavioral–environmental interactions, vector and non-human reservoir species involved in the disease system, and difficulties in isolating the impact of climate change from other significant environmental and human-driven changes (App. 4.6).

Evidence is growing that there are emerging mosquito-borne diseases and species that are able to transmit pathogens in the US. However, not all of these are linked entirely to climate change but also to land-use change, global trade, and importation of pathogens related to travel.

There is also a growing body of evidence exploring the bionomics of mosquitoes and ticks and the pathogens they carry to better understand the underlying mechanisms by which changes in thermal conditions could increase or decrease disease risk.[283]

Most projection models of range do not use disease but rather vector range as the endpoint. Arizona, for example, has an abundance of the dengue virus vector *Aedes aegypti*, but there has been little documentation of local transmission of dengue.[284,285] There is also uncertainty around how the mosquitoes and ticks themselves, as well as the pathogens they are carrying, will adapt to climate change.[76]

Uncertainty also stems from challenges with surveillance systems and data collection relating to heat injury and illness, especially in the occupational setting. As is the case with occupational data generally, data on and estimates of heat-related morbidity and mortality differ based on the source of the data.[286,287] Some heat-related impacts may not be properly categorized as heat-related[288] and may not accurately capture the location of exposure, as it may be reported either by the person's residence or by the location where medical treatment was sought.[289] Further, the Bureau of Labor Statistics estimates that its accounting of occupational injuries and illness are undercounted.[290,291] It is therefore challenging to estimate the true number of injuries and illnesses due to extreme heat, and heat morbidity and mortality are underreported.[139] Occupational health impacts from other climate hazards may also be underreported.

Recent cold spells in Texas (e.g., February 2021) and other regions have highlighted the impacts of cold weather on communities, including fatalities that resulted from cold weather exposure and power failures.[292,293] Whether such trends in cold spells will continue is uncertain,[294] but colder temperatures are associated with adverse health outcomes and increase the risks of death and illness.[295,296,297] Positive and negative health impacts arising from climate-related shifts in ice storms, blizzards, and cold spells are an area for future research.

There is little research on the long-term health impacts of wildfire smoke exposure in communities that face repeated wildfires or on human health harms, and associated costs, from exposure to compounding and cascading hazards. There is a lack of research exploring the pathways associated with drought and human health in the United States. The full range of mental health impacts of climate change and climate-related events is not yet fully understood.[298] Additional research is needed in all of these areas, including compounding events such as drought and flooding, to better describe the pathways that affect human health.

There are important administrative, logistical, and methodological challenges in assessing mortality and morbidity common to large-scale disasters and public health emergencies of any provenance. These challenges undercut the ability of practitioners to gather, report, and use mortality and morbidity data to save lives and protect health in the wake of a public health event, from the initial devastation through the long tail of recovery. Accurate and timely information about mortality and significant morbidity related to the disaster is the cornerstone of the efforts of the disaster management enterprise and will require holistic

data systems and new approaches in order to be more effective.[299] Specifically, there is not a standardized methodology for counting excess deaths during and after hurricanes, which can result in an underestimation of number of deaths (Figure 23.5).[300] Similarly, vector-borne, food-borne, and water-borne diseases are not fully captured in case numbers.[71,301] For example, cases of the rare, and typically fatal, primary amebic meningoencephalitis from exposure to the amoeba *Naegleria fowleri* have been documented farther north, although this conclusion is based on limited case numbers.[57] Thus, the true burden of climate-attributable health effects may not be known; more research is needed to quantify health impacts in relation to physical, mental, and spiritual health.

Description of Confidence and Likelihood

Based on multiple lines of peer-reviewed evidence, including field studies, laboratory studies, model projections, and systematic reviews, it is an established fact that climate change is negatively impacting the health of the US population. Based on the amount and quality of peer-reviewed research, it is *very likely*, with *very high confidence*, that climate-related hazards will continue to grow, increasing human health impacts across all regions of the United States. Adaptation and mitigation activities could reduce this impact and protect health; the scope and scale of these efforts will determine future confidence levels around health impacts.

Key Message 15.2

Systemic Racism and Discrimination Exacerbate Climate Impacts on Human Health

Description of Evidence Base

While all people in the US face health risks linked to climate change, some populations are affected sooner and more intensely.[269,302] This is because of differences in the number of and severity of exposures to climate hazards (Figure 15.5), sensitivity to these hazards, and ability to adapt (KM 20.3).[99] This Key Message outlines how ample peer-reviewed literature and data indicate that some populations disproportionately face environmental injustices, including impacts from climate-related extreme events. Systemic racism, discriminatory policies, and longstanding marginalization and disenfranchisement all contribute to increased climate vulnerability and to determining who bears the most climate risk.[99,303] Specifically, this Key Message outlines the peer-reviewed evidence behind climate change's disproportionate impact in the areas of community health, food and water systems, healthcare access and delivery, Tribal and Indigenous Peoples' health, persons with disabilities' health, African American and Latinx peoples' health, women's health, and sexual and gender minorities' health.

Major Uncertainties and Research Gaps

There is relatively little community-driven participatory research on the health impacts of climate change, which leads to a lack of full understanding of impacts on disproportionately at-risk populations. There may also be underreporting of health outcomes due to a lack of healthcare access in some communities. For example, the mechanisms causing certain demographics, such as Black and Latinx populations, to have an increased risk of contracting Valley fever are unknown. More research is needed to determine links among higher rates of occupational exposure, societal factors such as access to healthcare or health insurance, or genetics.[68]

There is limited data on well-water usage and quality in some states, and limited funding and capacity for water quality testing in disproportionately impacted communities.[304] Similarly, there is a research gap on

aspects of climate change impacts on food quality, security, and nutrition in the US, as much of the research focuses on developing countries.[305,306]

There is also limited research on system-wide health impacts, in which communities, ecosystems, and all living relatives depend on the holistic, intact system to survive and thrive.[307] Such understanding is important to ensure that adaptation does not happen in silos or isolation but rather includes the entire living system and that the proposed actions can actually achieve the intended results; this can determine the ability not only to survive but also thrive for generations to come. This is of particular importance to Indigenous communities.

More research could increase understanding of gender disparities for women and for sexual and gender minorities.[193] More research on risk factors and contextualized vulnerabilities could also provide better insights into acceptable prevention and control strategies that can be implemented to protect the health of disproportionately impacted populations. There is limited research exploring the unique vulnerabilities of women and gender minorities in pregnancy, as well as the impact on fetal outcomes.[1,308,309] Some studies demonstrate that women experience more significant health consequences, but very few directly relate them to climate change specifically.[197]

Research gaps at the intersection of disability, climate change, and health are impeding the development of effectual climate adaptation and mitigation policies and initiatives.[271,310] Participatory research is required to understand the climate impacts and health disparities experienced by the heterogeneous disability community.[271] Future climate-related health research can consider compounding multiple discrimination, including persons with disabilities, African Americans, Latinx, women, children, Indigenous People, older persons, and sexual and gender minorities.[178,271,310] A bottom-up approach to the development of public health responses with and by organizations of persons with disabilities may advance innovative public health approaches.[271] Additional research on the health effect of heat could demonstrate effectiveness of interventions for the diverse disability community.[271] Moreover, further environmental justice research inclusive of persons with physical and mental disabilities would assist climate adaptation and mitigation planning and initiatives.[311] A greater proportion of persons with ambulatory and cognitive disabilities were found to reside in neighborhoods with Hurricane Harvey–induced flooding in Harris County, Texas, many in public housing in non-White neighborhoods with low wealth; such research is vital to future disaster risk-reduction strategies.[312] Accurate health surveillance of morbidity and mortality among disability populations that have been marginalized, including persons with intellectual disabilities, is critical to ensuring disability-inclusive climate responses.[271] Additional research would improve knowledge of climate and health impacts on the Latinx population. The use of the term Latinx in the chapter is used to reflect gender diversity and is inclusive of nonbinary, gender nonconforming, and transgender individuals. The term Latinx is primarily used by younger generations and sexual and gender minorities.[313] Some literature suggests that the term should not be used because *x* is not common in the Spanish language, upholds a Western idea that gender neutrality is grammatically superior, and, when used to refer to all Latinx individuals, can erase Latinas similar to the way that "Latinos" does.[313,314,315] Other literature suggests that use of the term allows for individuals, who are often erased and discriminated against, to self-identify as a gender outside of or between the binary or who may not have a gender at all.[313] Use in this chapter is consistent with the inclusion of the sexual and gender minorities section and the CDC's adoption of the term "Latinx" when referring to health equity.[99] Additional community-based research to inform specific impacts on Latinx communities is needed.

There is limited data at the census tract level or similar geographic scale on social vulnerability and climate hazards. Figure 15.5 identifies specific counties with increasing trends in climate hazard–related economic loss that also are designated as vulnerable using the SoVI (Social Vulnerability Index), which synthesizes information across multiple variables at the county scale. It does not, however, fully capture the dispropor-

tionate impacts of climate hazards in specific neighborhoods or on specific population or cultural groups within a county, nor does it account for risk created by historic marginalization.

Furthermore, data suppression due to health privacy concerns can limit the availability of data for research on specific racial or gender groups. In addition, political sensitivities around the topic of climate change impacts on specific populations can hinder research and response.

Description of Confidence and Likelihood

It is unequivocal that some populations are already disproportionately impacted by climate change, as evidenced by multiple lines of data and peer-reviewed research that included longitudinal field studies. Research and data indicate that disproportionately affected populations include persons with disabilities, older adults, pregnant people, children, sexual and gender minorities, some communities of color, and those living in communities that have been under-resourced and over-burdened. Populations at higher risk will continue to be negatively impacted by climate change unless disparities are addressed and adaptation and mitigation strategies are targeted to benefit all communities and, in particular, those that have been marginalized.

Key Message 15.3

Timely, Effective, and Culturally Appropriate Adaptation and Mitigation Actions Protect Human Health

Description of Evidence Base

Multiple lines of research indicate that the health of the US population benefits from adaptation and mitigation activities, including integrated approaches to mainstream health into policies such as improvements in food, infrastructure, water, and sanitation. There is growing evidence that various adaptive strategies (e.g., cooling centers, building resilient healthcare infrastructure, communication campaigns, etc.) have an impact on knowledge, attitudes, and behaviors that can improve health.[269,316] For example, federal programs from the US Department of Health and Human Services (Low Income Home Energy Assistance Program) and the Department of Energy (Weatherization Assistance Program), as well as state governments, are implementing a suite of additional energy efficiency programs to help families reduce their energy costs and protect their health.[229] Recent research and limited literature reviews describe and classify the level of effectiveness of various adaptations and interventions to protect health.[316,317,318] This evidence informed the Key Message content related to adaptation. Additional research and evidence showing direct impact on human health outcomes would be needed to increase the confidence level to *very high*.

Peer-reviewed evidence indicates that strategies to reduce greenhouse gas emissions (mitigation) can protect health by reducing future climate hazards.[205] They also can increase resilience by providing co-benefits that immediately improve health.[319] The economic value of avoided hospitalizations and premature deaths are of the same order of magnitude as or larger than the cost of implementing the mitigation polices.[29]

Major Uncertainties and Research Gaps

There are still uncertainties and research gaps around timely, effective, and culturally appropriate adaptation and mitigation actions, including in the areas of risk management and integrated approaches, community-level resilience and adaptation strategies to build capacity, climate resilient and sustainable health systems, benefits of reducing air pollution, disease surveillance, and actions to protect populations from extreme heat, wildfires, and vector-borne diseases.

Further research could help document the effectiveness of adaptation and mitigation options in both the short term and long term. This could include examining the specifics affecting the success of interventions, including enabling conditions, constraints, and barriers, as well as effective approaches to overcome challenges and to scale up effective measures. Some mitigation and adaptation activities can have unintended negative health consequences; for example, trees planted to provide shade and reduce exposure to unsafe temperatures may inadvertently increase pollen levels and pose a hazard to those with respiratory health issues such as asthma.[320,321] Providing timely pollen information to clinicians, public health practitioners, and the public could increase awareness and allow at-risk individuals to take preventive measures (KM 14.4). Because pollen monitoring stations are sparsely distributed, using nontraditional data sources such as information from web searches[322] and near-real-time data on symptoms of emergency department patients[323] can offer alternative ways of gathering and communicating potential risks of pollen exposure.

There is also a lack of research on the effectiveness of some health-protective actions in different regions and among varying population demographics; for example, tree planting may not be a feasible strategy to provide shade in a water-scarce ecosystems such as the desert Southwest. More research would improve understanding on how individual and community-level social capital impacts the effectiveness of adaptation and mitigation strategies.[324] More research would also help tailor health communication messages to specific populations, an effective strategy to protect health.[325]

Continuous improvements in research and modeling can help drive evidence-based public health responses to minimize illness and death.[224,225,226] Climate-sensitive disease or health-outcome surveillance systems could be integrated with weather event tracking and economic cost estimates to assess the overall impact of such events.[31,326]

There is limited curriculum on the health impacts of climate change. Greater integration into medical school, nursing school, and public health curricula can increase awareness of the established links between climate change and health and effective adaptation and mitigation strategies to reduce these health impacts.[327,328]

Health departments are chronically underfunded, and most do not have the resources to prepare for and respond to the health impacts of climate change.[329] Increased capacity is needed to track hazards, build community resilience, and address cascading hazards. Improved data and capacity would allow for more effective adaptation and mitigation actions to protect health. Healthcare and public health worker shortages and unstable funding limit the ability of practitioners to engage in climate change–related health protection activities.

More research is also needed on community acceptability of adaptation and mitigation interventions to ensure effectiveness and sustainability. In addition, there are still gaps in implementation science ("the scientific study of methods and strategies that facilitate the uptake of evidence-based practice and research into regular use by practitioners and policymakers"[330]), a practice that helps ensure interventions benefit the communities that are most impacted by climate change.[99]

Description of Confidence and Likelihood

In the first statement of Key Message 15.3, the author team determined that there is *high confidence* that human health can be protected if adaptation measures are implemented. This statement is based on multiple lines of peer-reviewed evidence and real-world examples of successful adaptation strategies. Measures such as building energy retrofits, the establishment of education and outreach programs, installation of white roofs, and improvement of equitable access to cooling centers and green spaces can help protect human health if the necessary resources to implement these strategies exist or are made available. Based on peer-reviewed literature, there is also *high confidence* that creating climate-resilient health

systems will protect health and *high confidence* that mitigation efforts to reduce greenhouse gas emissions can protect health and improve health equity.

There is some uncertainty because it is difficult to determine future human behavioral response to the proposed adoption of adaptation and mitigation strategies. In order to improve health equity, it remains important to contextualize these strategies to specific communities, determine acceptability of strategies to specific communities prior to introduction, and investigate potential unintended consequences prior to adoption of mitigation strategies.

Fifth National Climate Assessment: Chapter 16

Tribes and Indigenous Peoples

Chapter 16. Tribes and Indigenous Peoples

Authors and Contributors

Federal Coordinating Lead Authors

Rachael Novak, Diné/Navajo Nation, formerly Bureau of Indian Affairs (through August 2023)
Matthew B. Laramie, Colville Confederated Tribes (Sinixt) and Bureau of Indian Affairs

Chapter Lead Author

Kyle Whyte, Citizen Potawatomi Nation and University of Michigan

Chapter Authors

Nicholas G. Bruscato, US Department of the Interior
Dominique M. David-Chavez, Taíno (Borikén) and Colorado State University
Michael J. Dockry, Citizen Potawatomi Nation and University of Minnesota
Michael Kotutwa Johnson, Hopi Tribe and University of Arizona
Chas E. Jones Jr., Affiliated Tribes of Northwest Indians
Kelsey Leonard, Shinnecock Nation and University of Waterloo

Review Editor

James Rattling Leaf, Rosebud Sioux Tribe and North Central Climate Adaptation Science Center

Cover Art

L.A. Jacobs, C. Avery, K. Champagne, R. Grayson

Recommended Citation

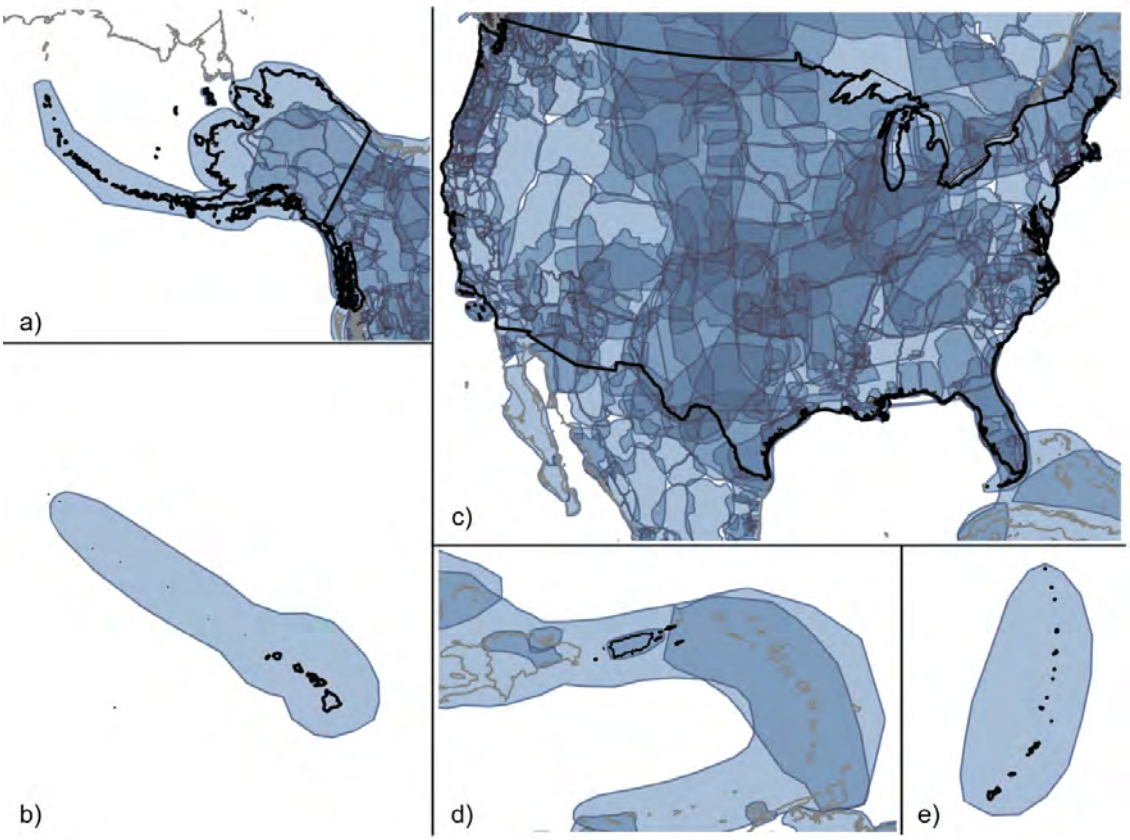
Introduction

Indigenous Peoples in the United States represent more than 700 communities and Tribal Nations. They are culturally and politically unique and self-determining societies in North America, Hawai‘i, American Sāmoa, Guam, the Northern Mariana Islands, Puerto Rico, and the US Virgin Islands (Figure 16.1), encompassing diverse ecosystems. They differ in their relationships with federal, state, territorial, and local governments but have similarly endured genocide and land dispossession (Figure 16.2). Indigenous Peoples' origins begin millennia ago, long before the United States. Many Indigenous persons are scientists of the environment, holding holistic understandings of the interconnected drivers of climate change and evidence of climate-related changes and strategies for adaptation (Figure 16.3; KMs 26.1, 27.6, 30.2, 30.5).[1,2,3,4,5,6] For generations, Indigenous Peoples have centered their knowledge of climate change in their cultures, political organizations, and arts. Many Indigenous persons closely track natural cycles and assemblages of plants and animals, making them keenly aware of environmental disruptions.

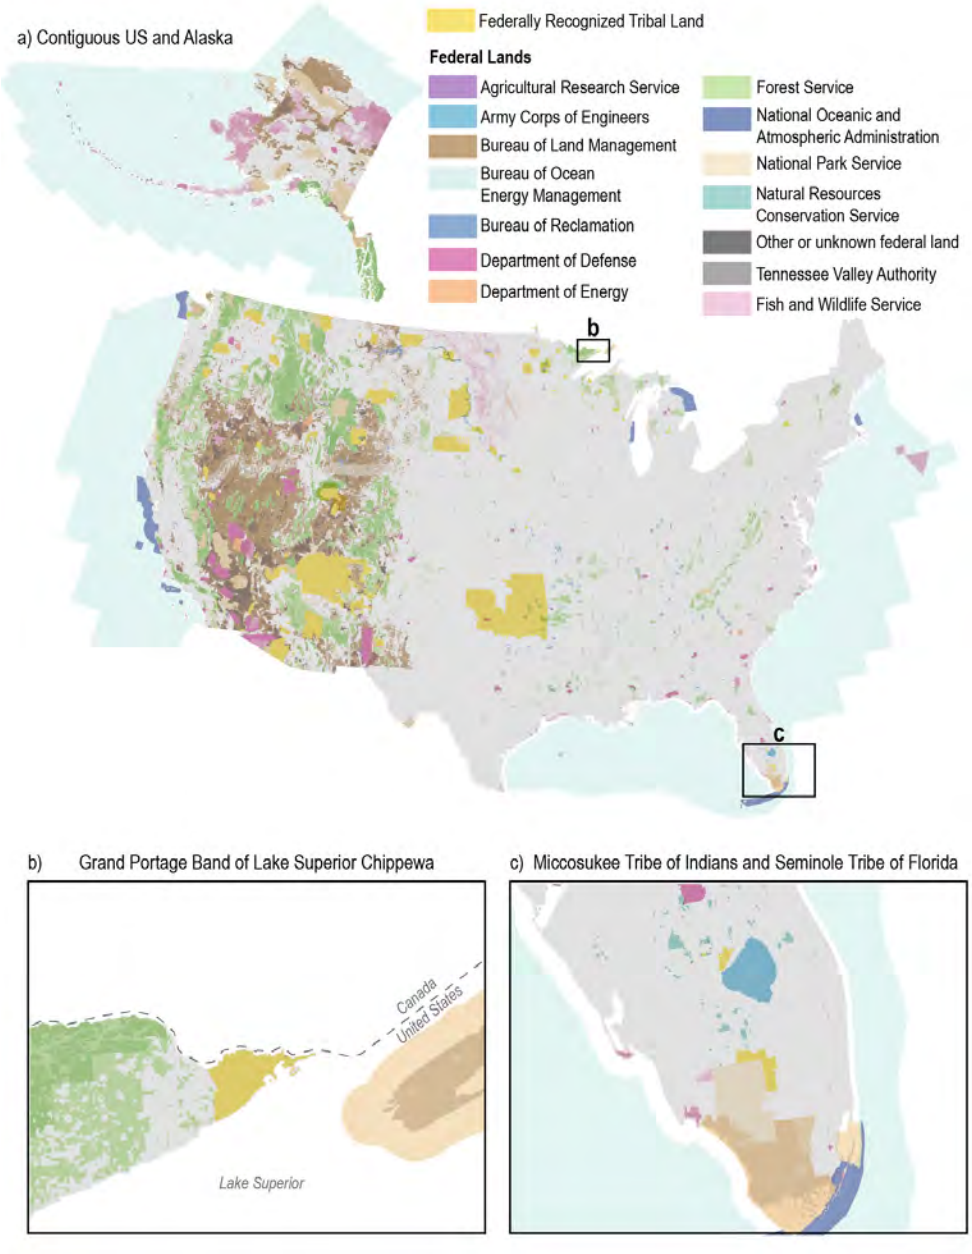
Representative Locations of Indigenous Peoples



Homelands of Indigenous Peoples are located throughout the US and its territories.

Figure 16.1. The maps show pre–United States customary (traditional) homelands and some US-recognized contemporary homelands. The maps represent overlapping territories (approximately represented in outlined, shaded areas, with darker shading representing areas of overlap) in North America (**a** and **c**), Hawai‘i (**b**), Puerto Rico and the US Virgin Islands (**d**), and Guam and the Northern Mariana Islands (**e**). The maps exclude most Indigenous marine territories. Given available data, the maps omit many territories (e.g., in American Sāmoa). Figure credit: Colorado State University, NOAA NCEI, and CISESS NC.

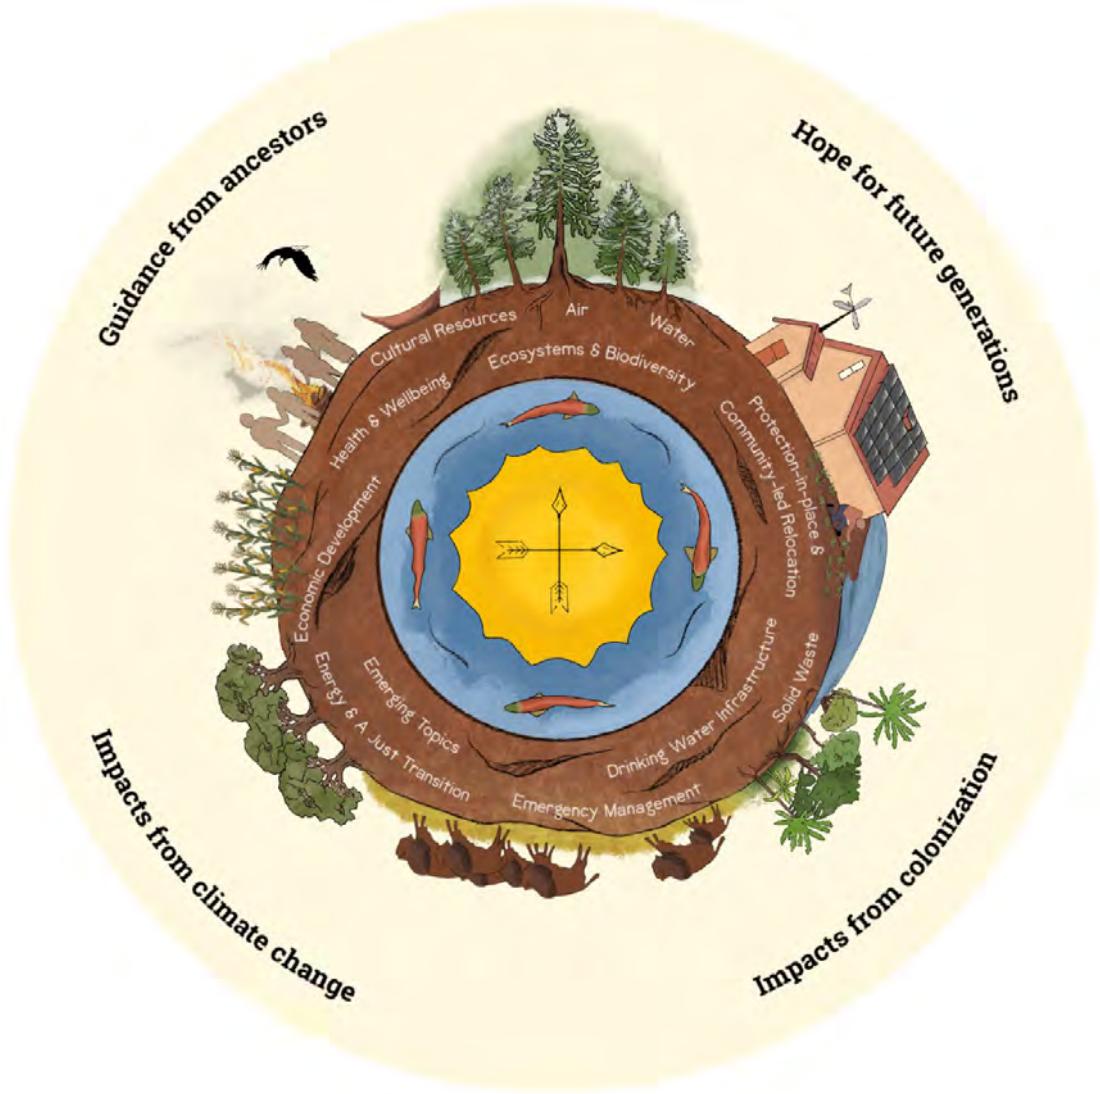
The Complexity of Land Tenure for Indigenous People



Federally Recognized Tribal Lands are often near federal lands, where Indigenous Peoples may have consultation, treaty, or comanagement rights.

Figure 16.2. The maps show many of the current federally recognized reservations in the continental US, including Tribal trust lands (and excluding fee lands and Hawai‘i, US Caribbean, and US-Affiliated Pacific Islands). Federal lands, including national parks, national forests, and wilderness areas, are shown, as Tribal Nations can have rights to comanage, exercise treaty rights, and consult on land management decisions. Panels (**a**), (**b**) and (**c**) show, in additional detail, the relationship between federal and Tribal lands. The profiles of (b) Grand Portage Band of Lake Superior Chippewa and (c) Miccosukee Tribe of Indians and Seminole Tribe of Florida highlight current and potential comanagement agreements between Federally Recognized Tribes and the Federal Government.[7,8] Figure credit: Citizen Potawatomi Nation, University of Minnesota, and DOI. See figure metadata for additional contributors.

Indigenous Holistic Worldview



Indigenous holistic worldviews offer diverse and complex expressions of climate change.

Figure 16.3. As an intentionally non-exhaustive example by particular Indigenous designers, the "Indigenous holistic worldview" image demonstrates interconnected drivers of sustenance, climate change impacts, and future aspirations. Illustrations connecting human social systems and the environment, including the relationship between social justice (e.g., colonialism, racism) and environmental change (e.g., ecological degradation, pollution), represent certain Indigenous approaches to climate change. Figure credit: ©STACCWG 2021.[6] Used with permission.

Indigenous Peoples have distinct rights to self-determination, cultural protection, and land use in relation to federal, state, and local government and nonprofit and for-profit institutions.[6] For example, Alaska Native corporations own and hold resource rights in one-tenth of Alaska lands for the purpose of economic development.[9,10] Alaska Tribal governments are responsible for managing government services, including cultural revitalization, for their members yet control significantly less land than corporations (see Ch. 29). Broadly, Indigenous-operated institutions include local customary and traditional governing systems, US Federally Recognized Tribes, treaty organizations, Alaska Native Corporations, Alaska Native villages, community development corporations and financial institutions, Native Hawaiian Organizations and

Hawaiian Home Lands, Indigenous-serving organizations within US territories, state-recognized Tribes, urban Indigenous centers, and more.

US federal and some state governments have agencies and programs with legal mandates to support Indigenous Peoples' health, economic vitality, education, environmental quality, and cultural continuance. The Federal Government has a legal obligation to consult with Federally Recognized Tribes and the Native Hawaiian community.[11,12,13,14] The US has given a non-binding endorsement of Indigenous Peoples' rights as articulated in the United Nations Declaration on the Rights of Indigenous Peoples, which affirms that Indigenous Peoples have rights to self-determination and free prior and informed consent regarding territorial development and the protection of their health, cultures, and knowledge.

Climate change negatively disrupts Indigenous Peoples' health (KM 15.2), economic vitality, education, environmental quality, governance, and cultural continuance (Figure 16.3).[6,15] Historical abuses of Indigenous rights have significant responsibility for the heightened severity of climate disruption.[6,16,17] The US government's taking of land from Indigenous Peoples has increased vulnerability to climate disruption.[18,19,20] The growth of the US industrial sector heavily polluted and degraded Indigenous territories through mining, fossil-fuel energy development and use, commodity and plantation agriculture, unsustainable forestry, and military infrastructure and activities.[21,22,23,24,25,26,27]

Today, Indigenous initiatives addressing climate and energy are often organized as movements for protecting and advancing Indigenous rights. These include rights to self-determination regarding climate change responses in their territories—rights that are critical to Indigenous efforts to choose the best pathways for supporting health, economic vitality, educational institutions, environmental quality, governance, cultural continuance, and spiritual traditions.

Key Message 16.1

Indigenous Peoples Face Risks to Well-Being and Livelihoods from Climate Change and Barriers to Energy Sovereignty

Climate change continues to cause negative effects on critical aspects of Indigenous Peoples' well-being, including their livelihoods, health, nutrition, and cultural practices, as well as the ecological resilience of their territories (*very high confidence*). Indigenous Peoples are responding in diverse ways, including through energy sovereignty (*very high confidence*).

Indigenous Peoples face harms and risks from climate change that negatively affect their health and well-being, economic sustenance, and cultural integrity and continuity (KMs 15.3, 25.3, 27.6, 29.1).[28,29,30,31,32,33] Given the diversity of Indigenous Peoples, no single chapter could adequately address projections of the impacts of climate change on many hundreds of communities 25–100 years in the future. In this Key Message, relocation, including permanent relocation and managed retreat, is covered as a separate topic. Many Indigenous Peoples continue to be among the communities navigating climate-related disasters and negotiating permanent relocation, expansion, community-led relocation,[34] and managed retreat (KMs 29.1, 29.4, 30.2). Indigenous Peoples face injustice in energy transitions and barriers to investing in renewable energy.[35,36,37,38,39] The information in this Key Message builds on the findings of Tribal and Indigenous Peoples' chapters in previous National Climate Assessments without repeating previous findings.

Indigenous Livelihoods and Economies

Indigenous livelihoods and economies often rely on combinations of subsistence systems, natural resource management, small businesses, nonprofit organizations, community development corporations and financial institutions, Tribal government employment and contracts, Tribal enterprises, and multinational corporations.[40] Regarding US indicators, Indigenous Peoples are disadvantaged in terms of income, employment, wealth, and access to adequate infrastructure, which has negative impacts on the availability of resources for climate response.[6,18] Despite disadvantages, Tribes manage complex governments and economies. For example, there are 87 Native American financial institutions (banks, credit unions, and loan funds) managing $8 billion (in 2022 dollars).[41]

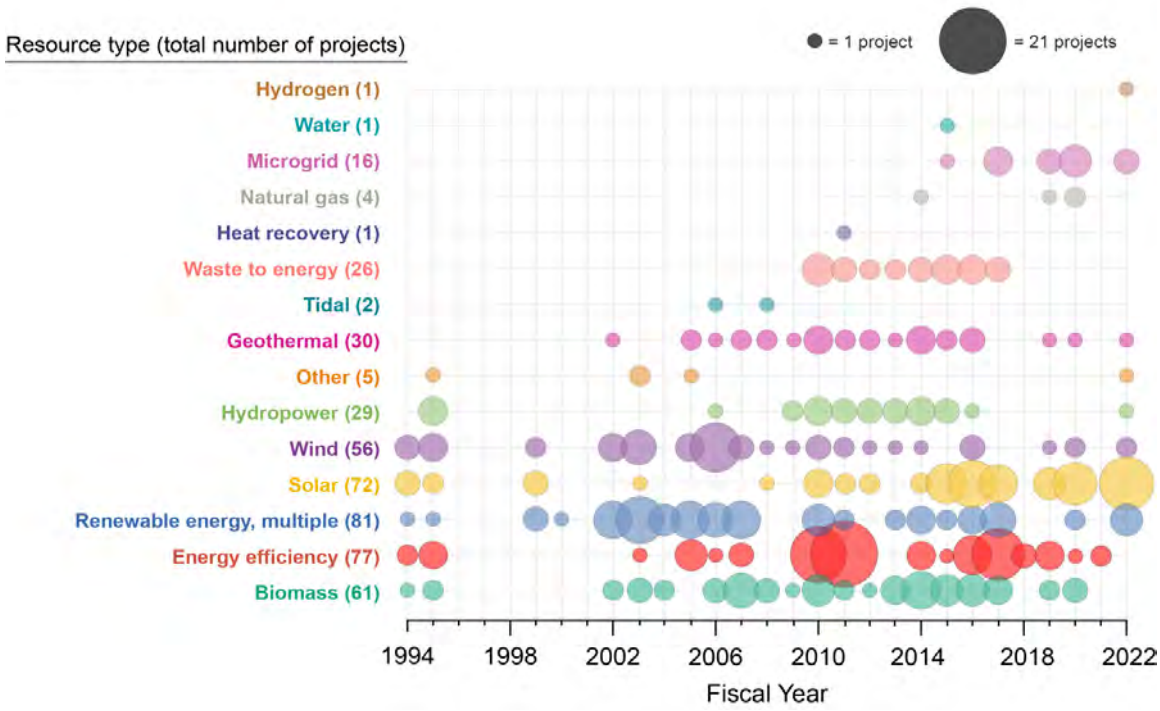
Climate change threatens to disrupt the conditions for critical Indigenous subsistence practices, including, but not limited to, planting, pollination, harvesting, the preparation and storage of food and medicines (i.e., medicinal plants), and subsistence-related travel (KMs 7.2, 10.2, 11.2, 21.3, 24.3, 29.3, 29.4, 29.5, 30.1, 30.2).[15,42,43,44,45,46,47,48,49,50,51,52,53,54] Other climate-induced economic disruptions to subsistence and business include losses of timber revenue from wildfire or declines in culturally important species used for activities like basketry,[55] berry harvesting,[56] fisheries,[57,58] and tourism (KMs 29.3, 30.3). Losses of subsistence lifestyles are associated with decreased capacity to cope with climate change.[59] Economic insecurity on subsistence and business can compound existing economic challenges,[60] including poverty, labor exploitation, colonial debts, and inaccessibility of finance mechanisms.[61,62,63]

Nonetheless, robust Indigenous economies and entrepreneurial enterprises provide paths toward greater Indigenous resilience. Revitalization of Indigenous agricultural practices are also linked to increased economic resilience and food security, such as Native Hawaiian loʻi and dryland agriculture.[64] In other cases, Indigenous People with strong ties to or ownership of successful and diverse economic enterprises have shown progress in their climate resilience.[65,66]

Indigenous Energy

Lack of capacity to transition toward renewable energy can be considered a vulnerability to climate change—that is, vulnerability to being excluded from unlocking the capacity to enact mitigation measures. Numerous factors affect Indigenous self-determination in renewable energy, including barriers to infrastructure ownership, access to financing and tax incentives, the navigation of regulations and jurisdictions, and income opportunities from renewables (KM 23.4).[39,67,68,69,70,71,72,73,74] Affordable renewable energy is often inaccessible to Indigenous households, inhibiting a just energy transition (Figure 16.4).[18,75,76,77,78]

Tribal Renewable Energy Projects



The breadth of project type and funding amounts have increased for federally funded renewable energy projects.

Figure 16.4. The figure shows federally funded Tribal renewable energy and energy-efficiency projects between 1994 and 2022. The size of the circles indicates the number of projects: the larger the circle, the more projects of that energy type were funded that year. Historically, projects like retrofitting to improve energy efficiency, as well as renewable energy projects including solar, wind, and biomass, often received funding. The more recent trend toward microgrid and solar projects mirrors efforts to build Tribal energy sovereignty. Figure credit: DOI, NOAA NCEI, and CISESS NC.

Health Risks

Indigenous concepts of health and well-being often remain closely tied to the health of the environment, waters, and more-than-human relatives that provide for subsistence and cultural needs (KMs 29.1, 30.2).[6,79,80] Climate change has decreased Indigenous Peoples' access to nutritious subsistence diets necessary for food sovereignty and security (KMs 21.4, 27.1, 28.3, 30.1)[47,49,50,81,82,83] and access to clean water (KMs 4.2, 30.1).[84] Climate change generally has had detrimental health impacts to Indigenous Peoples (KM 15.1).[85] Negative health outcomes and deaths have increased from extreme weather events, including heatwaves, flooding, changing ice conditions, hurricanes/typhoons, and wildfires (KMs 23.1, 30.2).[15,86] These negative health outcomes include post-traumatic stress disorder, anxiety, suicide, and other mental, spiritual, and social–emotional health challenges (KMs 15.1, 23.1, 29.1; Figure 29.3),[87,88,89] which can be exacerbated by intergenerational trauma[90] and breakdowns in family and community relationships.[85] These negative health impacts can amplify existing stressors on Indigenous health and well-being, including inadequate infrastructure, high rates of certain health conditions, high burdens of pollution, limited access to healthcare, water scarcity, poor sanitation, risks to occupational safety, and disproportionately high rates of environmental justice–related violence and human rights violations, many of which are especially burdensome for women (KM 4.3).[15,17,84,85,91,92,93,94]

Climate change and the COVID-19 pandemic have negatively affected Indigenous cultural, spiritual, physical, and mental health. In Alaska, pandemic-related travel restrictions limited food access, seasonal harvesting, and communal gatherings that maintain Indigenous Knowledge and practices around food systems, causing physical and mental health impacts.[95,96] High fuel prices and low salmon prices disrupted Indigenous businesses.[97] Broadly, food supply shortages and high costs during the pandemic compounded preexisting Indigenous food insecurities.[97,98,99,100] Preexisting water scarcity, such as in the Navajo Nation (KM 28.1),[101] Crow Agency, Montana,[85] and many Alaska Native communities (KM 29.1),[102] limited sanitation and hygiene practices and inhibited hydration and nutrition (KM 15.2).[101,103,104,105,106] During the peak periods of COVID-19 infection, disrupted stewardship and cultural activities included first salmon ceremonies,[97] canoe journeys,[99] wildfire response,[45] and Indigenous sports (e.g., stickball, lacrosse).[107] Some communities were able to engage in socially distanced and safe activities.[108] Climate change compounded preexisting inequities among Indigenous People who have low access to healthcare (KM 15.2)[85,109] and high risk of COVID-19 infection, hospitalization, and death.[110]

Culture

Climate change compromises Indigenous territorial integrity, spiritual values and practices, and lifeways essential to cultural heritage and identity (KMs 6.1, 10.1, 23.1, 26.1, 30.5; Box 1.3).[6,15,29] Climate-induced coastal hazards such as sea level rise, floods, storm surge, and erosion threaten Indigenous cultural sites, including burial grounds, sacred sites, museums, and other cultural infrastructure.[111,112,113,114] Climate change increasingly threatens the sustainability of culturally significant tree species used for making lodges,[115] totem poles,[116] basketry,[117] and maple syrup and sugar,[118] among other examples. As culturally significant habitats shift out of Indigenous jurisdictions, challenges arise for treaty rights, Native Hawaiian homelands, and other access rights.[15,80] Linguistically, some Indigenous place names that reference local geographic features, animals, plants, and first foods no longer accurately describe environmental conditions or associations.[119] Changes to sea ice in Alaska will make certain environmental words in the Inupiaq dialect of Wales obsolete.[120,121,122] These altered conditions could lead to health and safety concerns and significant cultural impacts.[28,122] Phenological changes impact the timing of culturally significant patterns in nature (KM 8.2). For example, the Indigenous Phenology Network formed to understand phenological changes on Indigenous lands throughout the US.[123]

Relocation

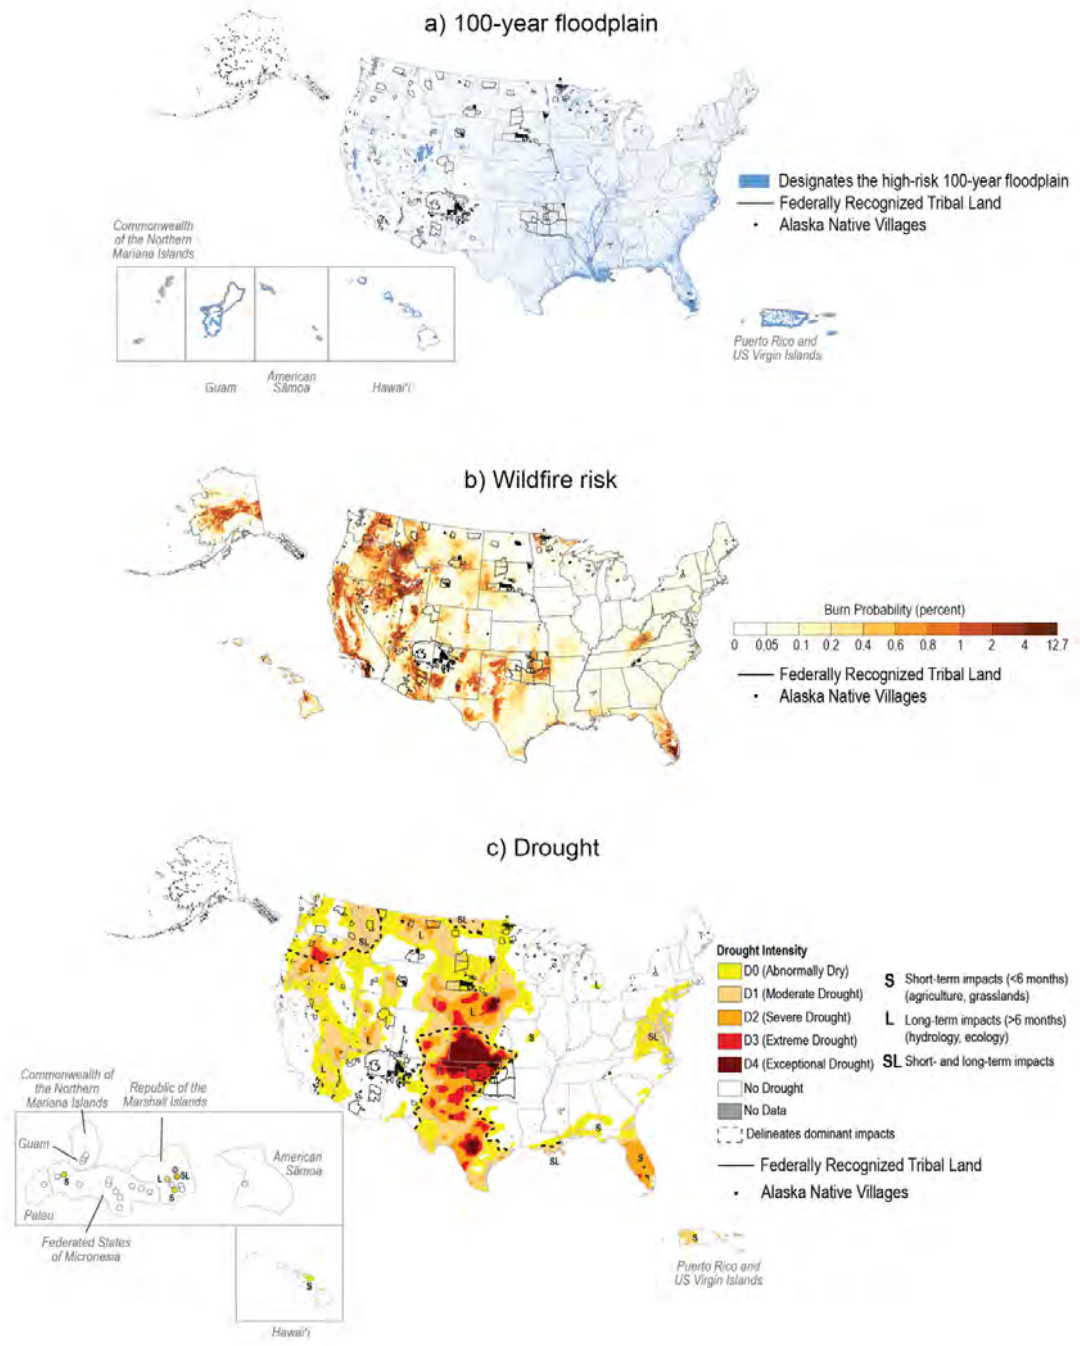
Indigenous Peoples, including Alaska Native villages, Pacific and Atlantic Coast Tribes, and Louisiana coastal Tribes, face unmet infrastructure needs and added stressors to culture and livelihoods as they relocate in response to increased erosion, more frequent flooding, increases in permafrost thaw, and rising sea levels (KM 29.2; Box 20.1).[18,114,124,125] Indigenous infrastructure is critical to supporting economies, sovereign security, and ways of life; it consists of a broad spectrum of human-built structures and facilities—from power grids to cultural and subsistence-related infrastructure—that are critical to the lives of Indigenous Peoples. According to the Bureau of Indian Affairs (BIA),[18] projected infrastructure costs arising from environmental impacts over the next 50 years are $4.8 billion for Alaska Native communities and a minimum of $2.1 billion for Federally Recognized Tribes (both amounts in 2022 dollars).[18] Seventy out of 200 Alaska Native villages face severe impacts from permafrost thaw, coastal erosion, and increased storminess.[126]

Indigenous Peoples in Hawai‘i, Puerto Rico, American Sāmoa, Guam, and the Commonwealth of the Northern Mariana Islands face distinct challenges for relocation based on their unique histories of colonialism. Often, impacts of climate change on US island regions and territories have been raised only in relation to impacts to life below water and not for Indigenous Peoples themselves.[127] Indigenous Peoples in US territories are often ineligible for federal funding for climate impacts, as well as international financing mechanisms due to their US affiliation.[128]

Most Indigenous Peoples face barriers to securing sufficient resources to implement climate adaptation, including home-building loans and complex technical data and training for decision-making (KMs 16.2, 29.4). Indigenous Peoples face intricate land policies that can prevent relocating or recovering their territorial bases, such as the US Supreme Court's decision in *Carcieri v. Salazar* (2009), which prohibited land restoration for certain Tribal Nations.[114,129,130,131,132]

When impacted by flooding, Indigenous Peoples do not receive equitable implementation of the National Flood Insurance Program (NFIP). The NFIP's inability to support a diversity of Indigenous jurisdictions and effectively communicate program information inhibits Indigenous Peoples' success as program operators and beneficiaries.[29] Indigenous Peoples face high costs through premiums, salaries for floodplain managers, and the expense of time and resources needed to develop, adopt, enforce, and maintain floodplain management ordinances.[133] They are required to pay into the NFIP even when they had been forcibly relocated by the US government to marginal, flood-prone land.[20,134,135,136] Indigenous Peoples are at risk of inundation and have limited ability to mitigate flood risk and manage floodplains, a circumstance made worse by the limits of available flood risk information. FEMA, EPA, and the US Army Corps of Engineers fund the development of flood-risk data (Figure 16.5a). However, historically inequitable and inconsistent delivery of data to Indigenous communities, including not honoring Tribal sovereignty, has prompted some Tribes to reject federally funded flood risk data and develop their own flood-risk data through university partnerships.[113,133]

Publicly Available Climate Data in Relation to Indigenous Territories



Some tribal lands are vulnerable to floods, wildfire, and drought.

Figure 16.5. These maps feature (**a**) EPA and FEMA's 100-year floodplain projections; (**b**) wildfire hazard potential through burn probability, which is the annual probability of wildfire burning in a particular area, also known as wildfire likelihood; and (**c**) drought intensity and duration of impact. Federally Recognized Tribal Land is outlined in solid black lines, and Alaska Native villages are indicated by black dots. Wildfire risk data were not available for the US Caribbean and US-Affiliated Pacific Islands. Figure credits: (a, b) FEMA, NOAA NCEI, and CISESS NC; (c) adapted from US Drought Monitor 2023.[137]

Key Message 16.2

Self-Determination Is Key to Indigenous Peoples' Resilience to Climate Change

By exercising their right to self-determination, Indigenous Peoples can respond to climate change in ways that meet the needs and aspirations of their communities (*very high confidence*). However, their ability to exercise this right is often undermined by institutions and policies shaped by the impacts of settler colonialism (*very high confidence*). Expanded support from federal and state governments has the potential to uphold Indigenous rights to self-determination for guiding climate resilience (*high confidence*).

Self-determination means Indigenous Peoples make decisions about how to respond to climate change in ways that meet community-defined needs and aspirations. Indigenous climate resilience requires having adequate options for deciding how to adapt to and mitigate climate change and the capacity to implement decisions and make strategic revisions upon evaluation. For many Indigenous Peoples, certain social and political conditions can support or curtail their capacity for self-determination. Indigenous self-determination has been limited by institutions and policies, colonial in their organizational structure, that enable federal, state, and local governments and private industry to make decisions for Indigenous Peoples and to maintain low levels of funding and administrative support for implementation.[4,54,138,139,140,141,142] The ramifications are very practical in nature, including a lack of sufficient high-speed internet, adequate roads, shovel-ready projects, and financial, grant, and project management resources and staff.

Self-Determination

Self-government is one application of self-determination. Although some Indigenous Peoples with self-government have rights recognized by the US, social and political conditions can curtail these rights.[138,143,144] Indigenous Peoples are often left out of cross-jurisdictional climate and emergency planning with federal, state, or local governments.[143] As an alternative, many Tribes have called for Indigenous-led management, as well as comanagement of lands, waters, and other resources currently under federal or state management. Comanagement, or even Indigenous-led management, represents opportunities to assert Tribal resource-management practices that address climate change.[145,146,147] Comanagement has been shown to be problematic if Indigenous capacities are not bolstered, communication is not clear and consistent, and Indigenous cultures are not uplifted.[148]

Consultation

For Federally Recognized Tribes, the US has a duty of government-to-government consultation.[149] Consultative processes, however, are not yet widely practiced in ways that empower Tribes, even when the US and its agencies increase the number of consultations.[14,148] In some cases where federal or state agencies hire Tribal liaisons, the liaison role is only a small percentage of those employees' full-time positions, and they often are responsible for establishing and managing relationships with numerous Tribes.[150] Federal agencies must consult with the Native Hawaiian community in relation to certain statutes, and in some cases other Indigenous organizations, such as Native Hawaiian Organizations, can consult with federal agencies. Indigenous Peoples without formal consultative relationships face barriers to voicing their knowledge and concerns in public-participation and stakeholder-engagement processes, curtailing their self-determination.[151,152,153] Climate change issues involve coordination and communication that must be underwritten by consultation.

Capacity Infrastructure

Indigenous Peoples can lack the needed staffing and workforce development capacities to fully implement climate change plans—efforts that can include applying for and managing grant funds, energy feasibility studies, natural resource assessments, hazard mitigation plans, environmental monitoring, legal efforts to enforce land, water and natural resource rights, and forest and natural resource protection and management (KM 23.5).[154] Funding is often not distributed in ways that Indigenous Peoples can access and benefit from, even during years when budget increases occur.[141] Funding may require matching funds, reimbursements, reporting requirements, degrees of shovel-readiness, or other administrative burdens that Indigenous administrative units cannot shoulder. This often results from lack of consultation of Indigenous Peoples in developing federal funding spending plans.[97,155] Tribal colleges and universities are often underfunded and face additional barriers to the accreditation necessary to train Indigenous community members in the academic fields related to climate change.[156]

Indigenous Peoples face compounding infrastructure deficiencies that threaten resilience—involving infrastructure tied to water quality and access, coastal shoreline protection, telecommunications and broadband, transportation, supply chain management, energy efficiency and access, and sustainable forest management (such as sawmills, secondary processing facilities, logging equipment, and staffing to operate and maintain infrastructure; KMs 23.4, 29.4, 30.3).[18,141] Indigenous Peoples face numerous barriers to accessing sufficient high-speed internet connections critical for education and capacity-building.[157,158] Coordinated infrastructure projects that mutually support one another would significantly advance Indigenous Peoples' resilience goals.[18] For example, Tribes have coordinated housing infrastructure programs with renewable energy projects[67] and community-level flood mitigation planning.[133,159] In Puerto Rico, community-coordinated efforts are working to serve energy and restoration needs (KM 23.5).[35,160]

Indigenous Data for Governance

Indigenous Peoples face challenges in accessing relevant data to support decision-making for climate resilience.[6] For example, they lack environmental data for Tribal lands and waters and often have access only to data that are misaligned with community values and priorities.[161] Indigenous advocacy for data ownership, protection, and access focuses on relevance to their peoples, cultures, territories, ancestors, traditional places, knowledge, epidemiology, and public health.[162,163] This includes ensuring that other parties seeking to collect and use data from or relating to Indigenous Peoples follow the principle of free, prior, and informed consent. Indigenous Knowledge holders and leaders call for more equitable relationships with scientists and support for Indigenous-led research.[164] The CARE Principles (Collective benefit, Authority to control, Responsibility, and Ethics) for Indigenous Data Governance, which emphasize Indigenous concerns and rights about data, are increasingly being applied in climate change–related projects.[161,165,166,167,168] Large US-based environmental data repositories, including the Earth Science Information Partners, are currently exploring methods for operationalizing the CARE data principles by improving data management capacity to ensure that data can be disaggregated, scaled down, and used to support Indigenous climate change planning.[161,166,169,170]

Indigenous Organizational Support

Indigenous organizations are important for carrying forward the messaging of their constituencies and providing additional unfulfilled services to communities. Indigenous urban centers provide large Indigenous populations in cities across the US—from New York to Los Angeles, Boston, Chicago, Phoenix, and more—with vital social services necessary for resilient urban populations in a changing climate (KM 12.4).[171] Inter-Tribal organizations and networks serve as resources for enhancing Tribes' climate change planning.[172,173] For example, the Intertribal Timber Council, Columbia River Inter-Tribal Fish Commission, and Great Lakes Indian Fish and Wildlife Commission are leading innovative climate adaptation research

in their regions and inspiring cross-cultural scientific collaborations with non-Indigenous researchers, scientists, and organizations.[144,174,175,176,177] Other organizations such as the National Congress of American Indians, United South and Eastern Tribes, and Affiliated Tribes of Northwest Indians support Tribes in their efforts to build climate resilience.[114,178,179] Indigenous businesses can provide climate services if offered equal access to contracts, opportunities, and information.[153] Indigenous organizations have sought to advocate for Indigenous perspectives, values, insights, and lived experiences of Indigenous Peoples by seeking to increase their access to appointed and elected leadership and decision-making positions.[180]

Key Message 16.3

Indigenous Leadership Guides Climate Change Response

Indigenous Peoples lead numerous actions that respond to climate change (*high confidence*). Indigenous-led organizations, initiatives, and movements have demonstrated diverse strategies for climate adaptation and mitigation that are guided by Indigenous Knowledges and values and by the pursuit of Indigenous rights (*high confidence*).

Indigenous-led actions to address climate and energy include implementation of climate adaptation strategies, climate and energy planning and policy initiatives, youth movements on climate justice, artistic mixed-media messaging about Indigenous experiences with and knowledges of climate change, and movements aimed to connect diverse Indigenous Peoples with one another spanning local to international scales (Figure 16.6).[6,80,138,181,182,183,184,185,186,187,188,189] Indigenous-led actions are often guided by Indigenous Knowledges, Indigenous values, and the pursuit of Indigenous rights to self-determination (Figure 16.3; KMs 2.3, 21.4, 24.4, 25.5, 26.3, 27.6, 28.3, 28.5, 29.7, 30.5).[190,191]

Indigenous Ingenuity the Hopi Way

Actions on climate change taken by the Hopi people engage science, tradition, and education.

Figure 16.6. For more than 2,000 years, the Hopi have been adapting to an average of 6 to 10 inches of annual precipitation. Seeds from corn, beans, melons, and squash grown in drought years are used again in dry years. Hopi children learn dryland farming and the values, customs, and identities of why they farm. (**left**) Hopi soil-moisture conservation techniques allow corn plants to adapt to extreme conditions such as drought. (**bottom right**) Hopi children in a traditional corn field learn about science through a cultural lens. (**top right**) A traditional Hopi sandstone home incorporates Western science with the use of solar and hydro panels. Photo credits: © Michael K. Johnson, University of Arizona.

Indigenous-Led Climate Initiatives

Many Tribes and Indigenous organizations have created climate plans. The Department of Energy has supported more than 190 Tribal-led energy projects, including many renewable energy projects (Figure 16.4). The BIA has funded many Tribal-led climate and energy projects, including 250 feasibility studies for renewable energy and hundreds of adaptation planning efforts (Tables 16.1, 16.2). Indigenous Peoples are including changing climate conditions in hazard mitigation plans (KMs 21.4, 25.2),[192] by incorporating available climate data (Figure 16.5), making them eligible for Hazard Mitigation Assistance grants through FEMA's Building Resilient Infrastructure and Communities program. Initiatives by the National Indian Health Board's Climate-Ready Tribes project, FEMA, the BIA's Tribal Climate Resilience program, the Tribal Climate Health Project, and the Institute for Tribal Environmental Professionals, among others (the Climate Adaptation Science Centers; the Climate Adaptation Knowledge Exchange, the Tribal Climate Change Project),[193] further capacities and expand funding.[159,194] The Institute for Tribal Environmental Professionals, for example, has created several levels of adaptation planning training, reaching more than 390 Tribes and more than 30 Tribal organizations.

Table 16.1. Number of BIA Tribal Climate Resilience Funding Awards Per Category

Cells with "n/a" for "not available" indicate years before an award category was offered. The categories include: 1, Trainings and Workshops; 2, Adaptation Planning; 3, Travel Support for Climate Adaptation Planning; 4, Ocean and Coastal Management Planning; 5, Travel Support for Ocean and Coastal Management; 6, Capacity Building for Scoping Efforts; 7, Relocation, Managed Retreat, or Protect-in-Place; 8, Internships; 9, Youth Engagement; 10, Implementation of Climate Adaptation Strategies; 11, Implementation of Community Relocation, Managed Retreat, or Protect-in-Place Actions; 12, Relocation, Managed Retreat, or Protect-in-Place Coordinator. Values indicate actual awarded amounts; no adjustments have been made for inflation. Funds for 2017 and 2018 were combined and awarded in 2018 due to delays resulting from governmental shutdown. Source: BIA.[195]

Some planning processes deliberatively start with place-based Indigenous Knowledge. For example, some adaptation plans involve interviews with knowledge keepers to determine key ecological indicators for adaptation strategies, such as the restoration of fire-adapted ecosystems, cultural burning, and strategies for maintaining biodiverse crops and culturally important species and landscapes (KMs 21.4, 28.5).[6,80,87,196] In terms of values, some Tribal energy projects emphasize renewable energy as connected to elder care by lowering the cost of household energy for elders.[67] Indigenous-led planning processes can emphasize that rights to self-determination should govern decision-making about climate and energy.[6,38,197]

Climate change responses guided by Indigenous Knowledges and values include restoration efforts, food security initiatives (Boxes 30.3, 30.4), climate emergency response systems, and innovative communication mediums. Examples include the Tribal Climate Adaptation Menu[80] and Indigenous-supported efforts, such as those of the Karuk Tribe[198] to ensure that the State of California has permitting requirements for vegetation management to reduce fire hazards through prescribed burns that have cultural value. In 2021, the Onondaga Nation completed construction of the Tsha' Thoñswatha' firehouse and community hall, which is the Nation's first triple-net-zero (energy, water, and waste) emergency-management facility (Figure 16.7).[199]

Tsha' Thoñswatha' Firehouse and Community Hall

The Tsha' Thoñswatha' firehouse and community hall in the Onondaga Nation relies on renewable energy and meets a net-zero standard of energy use.

Figure 16.7. The firehouse was designed in collaboration with the community and reflects the Onondaga Nation's language and culture. Photo credits: © Kelsey Leonard, University of Waterloo.

There are many other examples of Indigenous Peoples' climate adaptation efforts. The College of Menominee Nation developed a community-engaged phenology research project to understand changes in plants on their reservation and also developed the culturally grounded Menominee Theoretical Model of Sustainability (Figure 16.8)[51,200] to guide research, education, and community engagement. Other efforts include Indigenous-led blue carbon ecosystem restoration, such as through kelp farming off the coasts of Long Island and Alaska (Focus on Blue Carbon). The Swinomish Indian Tribal Community of Washington, among others, is building clam gardens as a climate adaptation strategy to combat sea level rise and ocean acidification and to bolster food security.[201] Native Hawaiians are restoring their agricultural systems, given the ability of native species to adapt to the changing climate.[64] Land-based and culturally grounded healing initiatives support Indigenous communities' resilience.[17,202,203] Indigenous self-determination protects the capacities of Indigenous People to practice stewardship and caretaking relationships with their land.[204,205] Indigenous Knowledge and values guide strategies focused on traditional species and the significance of their ecological relationships, the revitalization of management practices that were suppressed by the US Government, the uplifting of Indigenous cultural practices as a way to motivate people to engage,[79,206] and the well-being of community members who face severe risks and negative impacts from climate change.[207]

Climate Initiatives at College of Menominee Nation

Youth-Led Climate Movements

Youth-led movements (both US and international) continue to grow in number through the formation and engagement of organizations and coalitions, including the Climate Justice Alliance and the Indigenous Environmental Network, as well as through participation at the United Nations Framework Convention on Climate Change (UNFCCC) conferences of the parties (including the Paris Agreement).[208] The International Indigenous Youth Council was instrumental in leading the resistance against the proliferation of fossil fuel colonialism in Oceti Sakowin, historically known to some as the Sioux Nation.[209,210] Climate change was a key topic on the agenda at the February 2022 Native Youth Leadership Summit, held by The Youth Commission of the National Congress of American Indians.[211] Earth Ambassadors of United National Indian Tribal Youth Inc. have developed projects ranging from seed banking to waste management to address climate injustices facing their Indigenous communities.[212] Tribal colleges and universities are also engaged in building community resilience and supporting the next generation of climate leaders.[156,213,214,215] Another empowering youth-led initiative is Mni Ki Wakan, which is working towards Indigenous-led water justice for all.[216]

Art and Storytelling for Climate Communication

Since time immemorial, Indigenous Peoples have shared Traditional Knowledges and historical context through arts and storytelling. In modern times, they are mobilizing innovative and diverse media, including visual and performance art,[217] film,[218,219] podcasts,[220] radio (www.nativenews.net), and other forms of story-

telling, to communicate firsthand experiences of climate impacts and adaptation initiatives for Indigenous lifeways. Indigenous approaches to communicating about climate change are integral to the expression of cultural lifeways, sharing culturally appropriate examples of climate adaptation, and discussing Indigenized approaches to climate planning.

Local, Inter-Tribal, and National Collaboration

Indigenous Peoples' responses to climate change include collaborative environmental stewardship, protection, and coordination with other Tribes and Indigenous Peoples,[34] as well as with federal, state, and local governments, private organizations, and businesses (KM 12.4). In 2020 a collaborative Tribal-led nationwide effort was undertaken to review the Congressional Action Plan on the climate crisis[221] and to provide information, tools, and strategies for Tribal leaders to use in their advocacy on behalf of Indigenous Peoples.[18] For example, Tribes have coordinated with federal forests on regional fire management as a climate adaptation strategy.[6] Tribes and Indigenous Peoples continue to partner with each other to make unified statements and reports that can inform national and international climate policy and actions.[80,124,221] Inter-Tribal collaborations have engaged in regional monitoring of safety standards for shellfish and other resources.[6] Inter-Tribal consortia, such as the Midwest Tribal Energy Resources Association and the National Tribal Emergency Management Council, have fostered coordinated efforts to support the needs of individual Tribes. Indigenous nonprofit organizations, such as the NDN Collective, have produced funding programs and resources for Indigenous community-based organizations to access guidance and funds for renewable energy. Organizations such as the Indigenous Environmental Network have resisted the growth of the fossil fuel sector nationally.[222] Indigenous Peoples have participated in the conferences of parties of the UNFCCC (including the Paris Agreement), despite constraints to participation.[223] In 2019, the United Nations Educational, Scientific and Cultural Organization hosted a regional workshop titled "Mobilizing Indigenous and Local Knowledge Solutions: Addressing Climate Impacts and Vulnerabilities—A Perspective from the Caribbean Region," opening a dialogue and knowledge exchange across sectors, nations, and territories, including the US Caribbean.[191]

Traceable Accounts

Process Description

The authors of the Tribes and Indigenous Peoples chapter were selected based on their academic and government track records as experts on the topic of Indigenous Peoples and climate change in the US. Each author has a regional area of expertise in addition to expertise more broadly. The author team met virtually each week to discuss and cowrite the chapter. There was a weekly email update from the chapter lead (CL) to set the agenda for each weekly meeting five days in advance. The CL initiated discussion about the outline of each element of the chapter and received feedback from the chapter authors through email and through meetings. Revisions were made to the outline until agreement was achieved. The same process was initiated for the written content of the chapter and for each figure. After authors had contributed text, bibliographic references, and information and concepts pertaining to figures, the CL sought consensus through iterative communications over email and in meetings.

The Tribes and Indigenous Peoples chapter hosted one public meeting specifically on the chapter. The public comments from the meeting were reviewed and vetted for inclusion in the chapter. The chapter received comments from federal agencies, which the author team also responded to.

The author team has reviewed and included information from different types of credible sources relating to Indigenous Peoples and climate change. First, peer-reviewed scientific and academic literature on the topic was reviewed in its relationship to the US and its territories. Second, reports on the topic were reviewed if they met certain standards. They included the following: reports produced by Tribal governments, the US federal government, and state and local governments; reports produced by Indigenous organizations that have gone through a quality review process relevant to the particular information featured in the reports; and testimonies and eyewitness accounts by Indigenous People with climate change information. In cases where testimony and eyewitness accounts were used, appropriate recognition of the nature of the information was included in the Traceable Accounts.

Tribes and Indigenous Peoples in the US represent more than 700 communities and Tribal Nations that span the entire country and its territories. The communities encompass diverse regions and ecosystems. They differ culturally and have different relationships with the US, states, territories, and local governments. While different culturally, socially, and politically, Indigenous Peoples share comparable social circumstances. The circumstances include Indigenous Peoples' existence in what is now US territory prior to the establishment of the country; their distinct cultures; their having subsistence practices as a dimension of their economies, depending on the community or people; their living in lands today that are smaller than their ancestral land bases; and, depending on the community or people, their having endured environmental risks stemming from pollution and other environmental injustices, low investment in infrastructure by the US Government, and barriers to economic development. The social circumstances of Indigenous Peoples formed the basis of how the author team assessed information in this chapter. It is not possible to assess source material for more than 700 communities and peoples that are distinct ecologically, culturally, territorially, and politically. For this reason, the author team assessed as extensive a literature base as possible and drew on credible information to report information in the chapter that is relevant to the social circumstances of Indigenous Peoples. Throughout the chapter, the author team deliberately referenced Key Messages from other chapters relevant to Tribes and Indigenous Peoples; at the same time, the text is explicit that there is extreme differentiation across Indigenous Peoples.

Key Message 16.1

Indigenous Peoples Face Risks to Well-Being and Livelihoods from Climate Change and Barriers to Energy Sovereignty

Description of Evidence Base

There is a diverse body of peer-reviewed academic literature, reports, testimony, and eyewitness accounts that disclose information about how Indigenous Peoples are impacted by climate change, including risks and current harms and costs. While climate change may present opportunities for certain populations, the current literature on this topic suggests strongly that Indigenous Peoples are currently facing increasing risks and burdensome harms and costs. The Fourth National Climate Assessment (NCA4)[224] reviewed literature since 2014 on this topic. NCA4 had three Key Messages in the Tribes and Indigenous Peoples chapter, focused on Indigenous Peoples facing risks, harms, and costs tied to their economies and cultures, their health, and their capacity to respond to disasters and natural hazards. This Assessment took into consideration the literature published since NCA4—from 2018 onward. Additional literature was found as well on topics not covered in NCA4, including energy systems and COVID-19. The Status of Tribes and Climate Change (STACC) Report[6] and the Contribution of Working Group II to the Sixth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) were published in 2021 and 2022, respectively. Both include a thorough peer-reviewed assessment of climate change issues that Indigenous Peoples have faced in the context of the US since 2018. The two reports are comprehensive but not exhaustive of important climate change impacts that Indigenous Peoples face relating to climate and energy. There are approximately 460 million Indigenous Peoples throughout the world.

Major Uncertainties and Research Gaps

For this topic, the author team had the capacity to analyze quality information covering numerous Tribes and Indigenous Peoples. However, the available literature does not come anywhere close to covering the total population of Tribes and Indigenous Peoples. As a result, there are hundreds of communities whose relationship to climate change is not covered in this chapter.

Description of Confidence and Likelihood

Very high confidence is attributed to this Key Message for at least two reasons. First, one of the primary evidence bases being built on is the NCA. Since 2000, greater evidence has been analyzed about the vulnerability of Indigenous Peoples to climate change. NCA3 and NCA4 represented substantive advances in the documentation of this evidence. Since NCA4, other major scientific reports and empirically rigorous reports and technical contributions, including the reports of the IPCC[15] and the STACC Report,[6] have added further to the documented evidence. Second, scientists, Tribal staff, and nonprofit professionals have increased their publication of rigorous information on Indigenous vulnerability, and US Government agencies have advanced in their documentation of steps diverse Indigenous Peoples are taking to address climate change.

Key Message 16.2

Self-Determination Is Key to Indigenous Peoples' Resilience to Climate Change

Description of Evidence Base

The evidence base is an assemblage of sources that range from documents produced by Indigenous Peoples themselves to academic literature. This diverse literature on the impacts of climate change and the responses of Indigenous Peoples to climate change discloses information about the conditions that affect Indigenous Peoples' options for adapting to and mitigating climate change. Domestic Policy Council (2021),[139] NCAI (2019b),[4] and the US Commission on Civil Rights (2018)[141] provide information about Indigenous capacities to exercise self-determination, including critical information about infrastructural, financial, and administrative capacities. Warner et al. (2020)[14] and Washburn (2021)[147] offer important information about how policies that support self-determination in the form of comanagement and nation-to-nation consultation are important strategies for responding to climate change and other environmental issues. The emerging literature on data governance is well documented in David-Chavez et al. (2019)[161] and Carroll et al. (2020).[165]

Major Uncertainties and Research Gaps

Many of the conditions that create barriers for Indigenous Peoples in relation to climate change also affect other important areas, including political rights, education, health, and criminal justice. There continue to be gaps in research regarding how many total communities and peoples face particular climate challenges. However, some of the policies, governance mechanisms, and rights that are documented as barriers to Indigenous responsiveness to climate change pertain widely to Indigenous Peoples. There are also gaps in terms of being able to fully account for all of the adaptation and mitigation activities and processes that Indigenous Peoples are a part of or leading.

Description of Confidence and Likelihood

Very high confidence is attributed to the statement that options for responding to climate change can be enhanced through support for self-determined decision-making. Within and beyond the available literature on climate change, the most common guidance from Indigenous and non-Indigenous sources is that Indigenous sovereignty, self-determination, and (where possible) self-governance are integral to supporting Indigenous efforts to address climate change. The author team discovered no literature claiming that US paternalism or domination of Indigenous Peoples is a pathway for mitigating climate risks and establishing renewable energy. *Very high confidence* is attributed to the statement that various institutions and related policy undermine or erode sovereignty and self-determination of Indigenous Peoples, negatively impacting opportunities for climate resilience. The literature, both since 2018 and before, depicts extensively and acutely the sources of barriers for Indigenous Peoples to address climate change and energy issues. There are no barriers that were discovered that operate independently of the influence of US colonialism on Indigenous Peoples. The final statement, on the relationship between federal and state support of Indigenous Peoples' self-determination, is assessed at *high confidence*. The available information and evidence demonstrate ways that such support can improve Indigenous self-determination; however, such improvements depend on how federal and state support is administered, such as avoiding measures that would foster problematic forms of dependence that would actually counteract the right to self-determination.

Key Message 16.3

Indigenous Leadership Guides Climate Change Response

Description of Evidence Base

The evidence base includes some academic and scientific articles in addition to many reports from Indigenous Peoples on how they are responding to climate change. This Key Message is limited to describing known information about what Indigenous Peoples are doing in response to climate change. The reviewed literature, which is extensive, provides information on a topic area that is little represented in scientific assessments and provides information about climate change adaptation and mitigation measures that Indigenous Peoples have taken recently. In the NCA4 Tribe and Indigenous Peoples chapter,[29] the Bureau of Indian Affairs and the author team for that chapter created a graphic representation (Figure 15.1 in NCA4)[29] of actions that Indigenous Peoples have taken to respond to climate change. The chapter text itself did not devote a Key Message to describing the responses. That is, the chapter did not have focused treatment on the topic of how Indigenous Peoples are responding to climate change. The Key Message for the current chapter includes additions to the graphic, which is featured again in updated form. The author team searched extensively for cases of Indigenous responses to climate change, and this Key Message reflects the results of what the author team learned about the array of information and evidence. The STACC Report[6] provides dozens of small case studies of Indigenous Peoples' actions, and the Indigenous Environmental Network and Oil Change International report on mitigation provides cases of Indigenous advocacy against certain drivers of human-caused climate change.[222]

Major Uncertainties and Research Gaps

Given that few climate change studies and scientific assessments take up and synthesize Tribal and Indigenous responses to climate change, this is one of the first assessments to describe the diverse array of responsive actions taking place. While the evidence base is extensive, there are certainly more responsive actions that Indigenous Peoples are engaged in that have not been published either at all or in a form that can be referenced in NCA. It is not known how many more cases there are. Indigenous Peoples, whether working through governments, organizations, or other entities, sometimes may not publish reports or publicly document the actions that they are taking. In other cases, documentation of an action may not be intended to be publicly referenced by its authors. And some publications, regardless of their quality, may not adhere with the requirements NCA has established for its evidence base.

Description of Confidence and Likelihood

The Key Message attributes *high confidence* to the evidence that Indigenous Peoples are involved in diverse strategies for climate adaptation and mitigation and that Indigenous Knowledge, values, and rights shape many of the strategies. The literature on climate change demonstrates the importance of relevant and trusted leaders in orchestrating solutions that communities and staff will support. Indigenous leaders, Tribal governments, and Indigenous organizations have such relevance and potential for trustworthy leadership. Given that the legal, cultural, social, and political circumstances of Indigenous Peoples vary widely, the solutions that Indigenous Peoples are pursuing are unique in that they are tailored to such circumstances. There were no discovered instances where Indigenous Peoples' solutions were not so tailored.

Introduction

Globally, climate change is rapid and widespread and will continue through midcentury even if emissions are cut sharply, intensifying events such as extreme heatwaves, heavy rainfall, and drought.[1] The acute and accelerating impacts outside of US borders on food systems, health, human well-being, built and natural systems, and economic sectors[2] affect US national interests and compound the impacts of warming within the United States. The pace of emissions reduction and adaptation response would need to accelerate this decade both to limit warming to 1.5°C (2.7° F) or 2°C (3.6° F) above preindustrial levels and to build resilience to existing and future climate impacts (KMs 2.3, 32.1).[2,3]

In a globally connected world, climate impacts can affect multiple sectors at once and have cascading effects that cut across sectors and geographies (KM 17.1). The direct impacts of climate change globally on people, ecosystems, and infrastructure, as well as the global transition to cleaner, lower-emissions technologies and economies, affect critical US interests including national security (KM 17.2); economics, trade, and investment (KM 17.3); and sustainable development (KM 17.4).

Despite documented evidence of increasing climate change risks, mitigation and adaptation responses by public and private sectors are not yet sufficient to avoid rising losses of life, biodiversity, infrastructure, and economic opportunity.[1,2] Proactive early adaptation and mitigation action can reduce losses from climate change and extreme events, avoid locking in high emissions, and produce economic, social, and environmental benefits.[4] In particular, inclusive approaches can help reduce risks, improve effectiveness of responses, and create opportunities for Indigenous Peoples, local communities, and other marginalized and underrepresented populations (such as women, youth, older adults, and ethnic minorities) who are especially vulnerable to climate impacts and energy transitions (KM 31.2). Adapting to a changing climate depends in part on the effective integration of climate information into decision-making at global, regional, national, and local levels (Box 17.1; KM 31.4).

Box 17.1. Climate Services at the International Level

Risk governance in the 21st century requires coherent actions across disaster risk reduction and climate change adaptation.[5,6] Systematic, coordinated approaches to climate information services (hereafter "climate services") can enable the development, quality-assurance, accessibility, stakeholder engagement, and knowledge-tailoring needed to support decision-making, from disaster risk reduction to resilient infrastructure development.[7,8,9] Climate services involves organizing different types of climate information (e.g., extreme-event return periods, slow onset trends such as sea level rise, in situ risk mapping, satellite-based data) across multiple timescales (e.g., weeks, seasons, decades, and longer), as well as technical assistance to help decision-makers interpret and integrate such information and related uncertainties into their planning and design processes. Such services support the coordination and implementation of international instruments and frameworks in which the United States has strong interests, including the Paris Agreement on climate change, the Sendai Framework for Disaster Risk Reduction 2015–2030, and the United Nations Sustainable Development Goals. Climate services are a central pillar of both the US President's Emergency Plan for Adaptation and Resilience (PREPARE), and the United Nations Secretary-General's initiative on Early Warnings for ALL (EW4ALL), launched in 2022. The EW4ALL goal is to ensure global coverage of action-oriented information systems to anticipate and reduce weather- and climate-related disasters by 2027.

There has been notable recent progress in data availability, including satellite-based information, climate- and disaster risk–related analytics, and networks for engaging communities across sectors such as national security, humanitarian interventions, water resources, human health, energy, food security, and infrastructure planning.[2,10,11,12] Examples include the Global Framework for Climate Services (GFCS), the European Union Copernicus Climate Change Service, Enhancing National Climate Services, and the Famine Early Warning Systems Network. The GFCS was initiated in 2009 and formally endorsed by the 187 member countries of the World Meteorological Organization, including the US.[8] However, many regions and countries lack sufficient capacity to assess climate impacts and cascading risks and to develop and deliver climate services to inform their immediate risk management and longer-term resilience goals.[13,14,15,16,17] While fundamentally important, observing networks are often inadequate in many regions. Many countries also lack comprehensive data on the local-level impacts of climate extremes and changes, hampering effective co-development and sustained delivery of services (KMs 31.3, 31.4; Ch. 23).[18] These gaps can undermine confidence in national and international climate service providers, sending users in search of alternative, competing, and less authoritative services, and, critically, can increase marginalization and inequity.

Key Message 17.1

Interdependent, Systemic Climate-Related Risks Increasingly Affect US Interests

In a globally connected world, climate change impacts on US interests are multifaceted, interconnected, and frequently exacerbated by social unrest and environmental degradation (*likely, high confidence*). The scale and speed of climate-related impacts to US interests are expected to increase, due in part to underlying interdependencies and to the projected intensification of climate change (*likely, high confidence*). Emerging systems- and scenarios-based approaches to integrative planning are being applied to account for interdependencies and competing priorities (*likely, high confidence*).

Climate-related risks manifest across multiple systems, sectors, geographic domains, and timescales.[19,20] Climate shocks in one or several parts of the built or natural system can lead to ripple effects around the world.[21,22] Climate change impacts—alone or in combination with compounding stressors—can cascade across interdependent systems, magnifying risks not typically attributed to climate change. The effects of these impacts can spill across geographies and markets and, in turn, affect multiple US security, economic, and sustainable development interests (Figure 17.1; Focus on Compound Events). Moreover, traditional approaches to managing risk are inadequate given the compound and cascading nature of system risk,

increasing the importance of accounting for system interdependency and uncertainty to reduce risk to US national interests.[23,24]

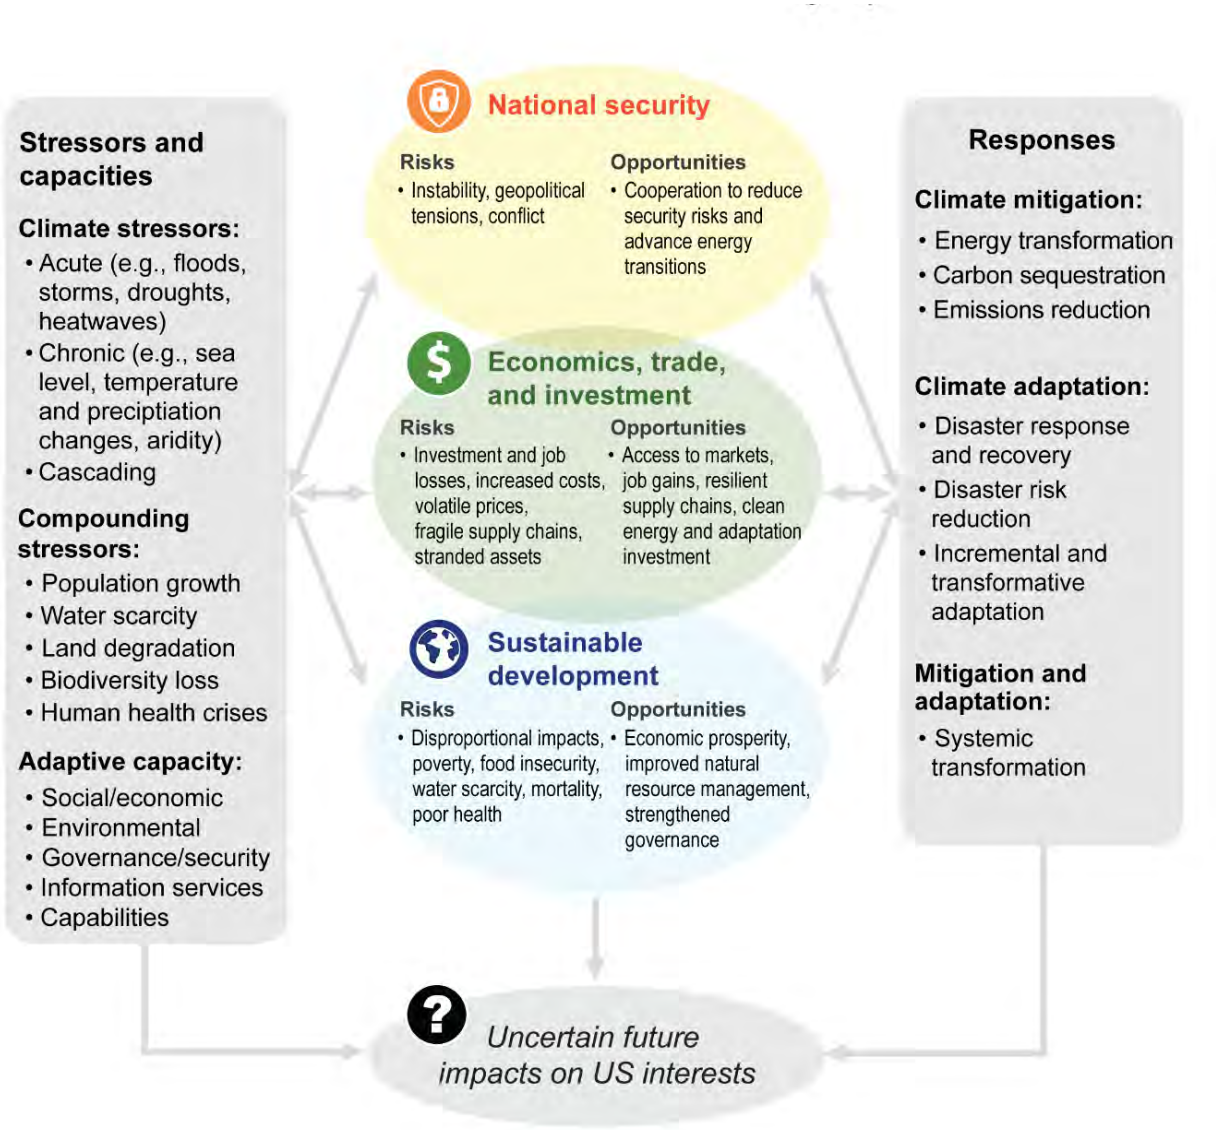
Climate change impacts affect the US's security, economy, and sustainable development interests by reducing local and global stability, disrupting livelihoods and economic growth, increasing poverty and global inequality[25,26] and compounding existing risks across US interests. For example, the Central American countries El Salvador, Guatemala, and Honduras are highly dependent on climate-sensitive agriculture, and climate change impacts disrupt rural livelihoods, health, and food security.[27] Drought and extreme storms have impacted millions of Central Americans by exacerbating conflict and insecurity, requiring significant humanitarian resources and fueling unprecedented migration, including to the United States.[28,29,30,31] Drought and extreme storms in Central America are expected to increase in frequency and severity due to climate change, threatening to further exacerbate these challenges.[32]

The combination of systemic global interdependencies and intensification of climate change is expected to increase both the scale and speed of climate change impacts.[1,33] Climate change—including increasing temperatures, changing rainfall patterns, and increased frequency of some extreme events—combines with stressors such as conflict, land degradation, biodiversity loss, population growth, and worsening human health to exacerbate food insecurity and potential famine.[34] For example, climate extremes have increased the incidence of multiple concurrent or consecutive breadbasket failures (e.g., poor harvests in major food-producing regions), threatening global food security and leading to cascading effects (e.g., social unrest and higher prices) across multiple geographies that affect US interests.[21,35,36] Since 2018, multiple stressors, including droughts in North America and the Horn of Africa, poor harvests in China and France, the COVID-19 pandemic, and the war in Ukraine have combined to severely test global food security, increasing fertilizer costs and food prices and decreasing food availability.[37]

Given the right conditions, however, interconnectedness can help mitigate risk. For example, food imports can address localized food insecurity and may become more prevalent given climate change impacts.[20,38] Transformative changes in human behavior that lead to "positive tipping points"—including the adoption of new technologies (e.g., energy transition to lower-emissions technologies) or approaches (e.g., regenerative agriculture approaches that increase climate resilience and sustainability of farm and food systems)—can help prevent the worst-case impacts of climate change.[39]

Traditional risk assessment and management approaches tend to focus on single sectors or locations rather than systems and the related complex interdependence of risks.[16,40] However, approaches to decision-making that address adaptation and mitigation early in the process at a systems level, considering the fullest suite of risks, interactions, and optimal response options, are advancing (Ch. 18).[41] Integrating responses vertically (across global, regional, and local levels) and/or horizontally (e.g., multistakeholder partnerships to codesign landscape-scale responses) offers promising insights for addressing these interdependencies across multiple scales and sectors.[42,43,44,45] Scenario planning, "nexus" approaches that address multiple sectors, and other co-development and participatory approaches are being applied to plan in the face of uncertainty, address linkages, and consider the role of response options themselves as risk drivers (Chs. 18, 31).[20,40] More experience is needed in applying and evaluating these emerging approaches to improve policy coherence and coordination across sectors and to better understand sensitivity to system changes and uncertainty.[40,46]

Interconnected Interests and Cascading Impacts



Future impacts to US interests are uncertain given complex system interdependencies and interactions between stressors, capacities, and responses.

Figure 17.1. This figure illustrates how system interdependencies and the interconnected nature of climate change stressors and response choices can lead to uncertain future impacts on US interests (e.g., national security; economics, trade, and investment; and sustainable development). Climate and compounding stressors interact and present different degrees of potential impact to US interests given varying levels of adaptive capacity, sensitivity of interest areas, and the effectiveness of responses in addressing systemic risks and taking advantage of opportunities. The complexity of interacting stressors and interdependent systems can lead to cascading impacts, unintended consequences, and increased uncertainty on future impacts to US Interests. Adapted from Ringsmuth et al. 2022[47] [CC BY 4.0].

Key Message 17.2

Climate Change Exacerbates Risks to National Security

Climate change can contribute to political and social instability and, in some instances, to conflict (*likely*, *high confidence*). It impacts the operations and missions of defense, diplomacy, and development agencies critical to US national security (*very likely*, *high confidence*). The US Government, bilaterally and in collaboration with international partners, is increasingly addressing these implications through a range of diplomatic, development, and defense responses (*very likely*, *high confidence*).

Climate change exacerbates existing security challenges and risks, affecting a wide range of US national security interests.[48,49,50] Climate change impacts and responses can contribute to political and social instability as well as various forms of conflict.[2,49,51,52,53] Security-related concerns can also stem from the impacts of climate change on human lives and livelihoods, food and water security, biodiversity, and ecological and human health, as well as the responses to these impacts.[54,55,56] Inversely, conflict can exacerbate climate-related vulnerabilities, particularly affecting women, children, and overburdened populations.[57] This interplay between climate and conflict can hinder both mitigation and adaptation progress. The risk of destabilization and conflict connected to climate change has implications for US security interests distributed worldwide.

As shown in Table 17.1, the climate risks to US security interests span from local instability to geopolitical tension. In addition to the risks of instability and conflict, compounding dynamics include declining agricultural production and food security;[2] recruitment and influence for extremist or violent groups;[58] and declines in state capacity or legitimacy, including potential corruption, where governments cannot effectively respond to extreme weather events or long-term, chronic climate-connected impacts.[59,60,61]

Table 17.1. Climate Risk Assessment to US Interests

"Risks to US national security interests through 2040 will increase as countries respond to the intensifying physical effects of climate change."[50] For a full explanation, see the National Intelligence Estimate on "Climate Change and International Responses Increasing Challenges to US National Security Through 2040,"[50] from which this table is adapted.

Risk		2021	2030	2040
Climate Effects Impacting Country-Level Instability	Strain on energy and food systems	Low	Medium	High
	Negative health consequences	Low	Medium	Medium
	Internal insecurity and conflict	Low	Low	Medium
	Greater demand for aid and humanitarian relief	Medium	High	High
	Strain on military readiness	None	Low	Medium
Climate-Exacerbated Geopolitical Flashpoints	Miscalculation over strategic competition in the Arctic leading to conflict	None	Low	Medium
	Cross-border water tension and conflict	Low	Medium	High
	Cross-border migration attributed to climate impacts	Medium	High	High
	Ungoverned unilateral geoengineering	None	Low	Medium
Geopolitical Tensions over Climate Responses	Perception of insufficient contributions to reduce emissions	Low	Medium	High
	Carbon dioxide removal not at scale for countries' net-zero pledges	None	Low	Medium
	Developing countries' demands for financing and technology assistance	Medium	High	High
	Petro states resisting clean energy transition away from fossil fuels	Low	Medium	High
	Competition with China over key minerals and clean energy technologies	Low	Medium	High
	Contention over use of economic tools to advance climate interests	None	Low	Medium

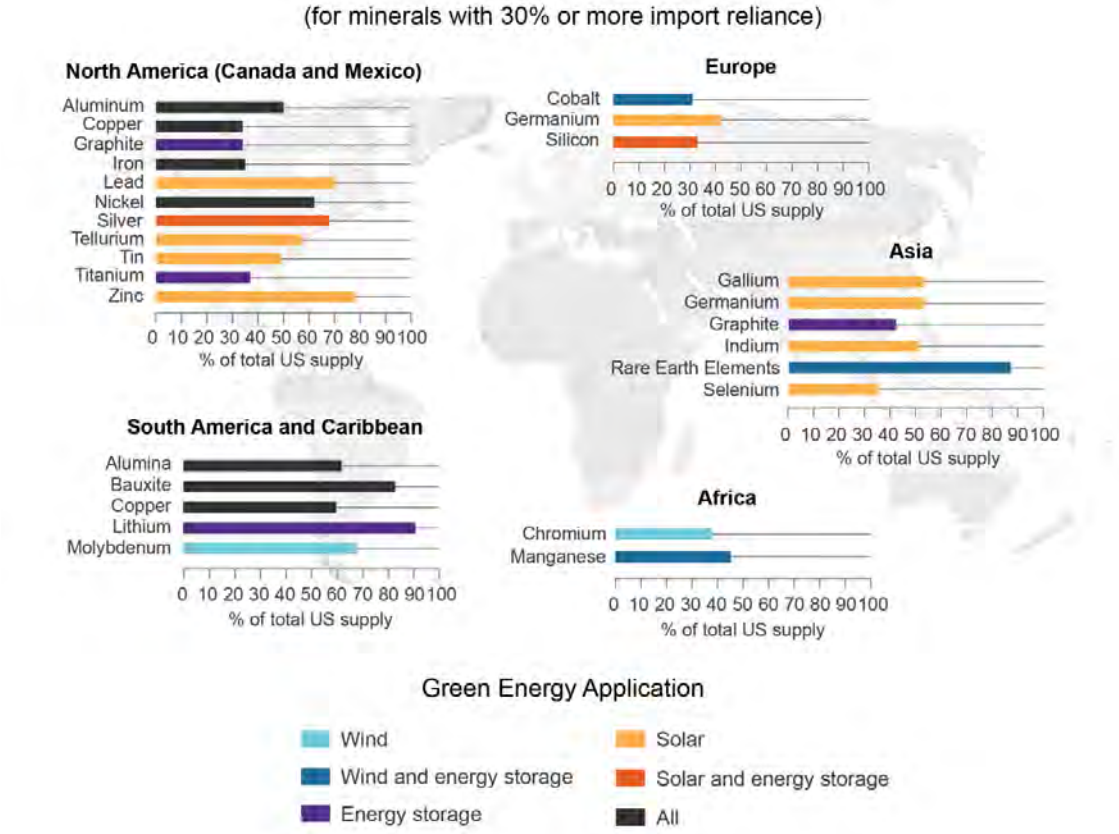
Mobility, both planned and forced, is a common adaptation response to a changing environment, contributing to displacement and migration that primarily occurs within countries and, at times, crosses national boundaries.[31,62,63] Climate change–related mobility, impacting both sending and receiving populations, is expected to increase.[50] Ongoing international engagement continues around climate change and mobility, but limited international governance that provides binding protections for people crossing national borders due to climate change results in varied state and regional responses.[64]

As countries continue to work toward adaptation and mitigation goals, alternative climate interventions are being considered to reduce the warming effect of greenhouse gases and avoid tipping points. One category

of alternative intervention is carbon dioxide removal, technical interventions to remove carbon dioxide from the atmosphere that can have impacts on food systems, biodiversity, and other systems (Chapter 32). Solar radiation modification (SRM) constitutes a variety of approaches to reduce sunlight reaching the lower atmosphere. The potential risks and benefits involving the use of SRM need to be considered relative to the risks and benefits associated with plausible trajectories of ongoing climate change not involving SRM.[65] SRM represents an area of growing interest for national security given the potential for unilateral action from state and non-state actors, evolving understanding of climate and societal impacts, and limited formal or informal mechanisms of engagement.[66,67] Understanding the risks and trade-offs of these alternative climate interventions is a rapidly growing field of study.

Climate change impacts are of particular concern in areas with limited resilience, unequal resource distribution, and/or weak governance structures. Unintended consequences of climate responses can also have important national security implications. For example, mitigation and adaptation efforts can unintentionally exacerbate new or existing conflicts and inequalities affecting marginalized populations.[68,69] Dynamics accompanying an energy transition such as price variability, loss of employment in the fossil fuel sector, and stranded assets for petroleum-producing countries may also contribute to internal protest and reduced support for strengthening international climate change mitigation efforts.[70] International climate change responses are shifting geostrategic and regional interests and priorities. These dynamics include competition for minerals and metals critical for mitigation and renewable energy.[71,72] Figure 17.2 displays the source of these materials, many of which are sourced outside the United States; however, note that China controls much of the market for mining and processing of many of these minerals and metals, leading to heavy dependence on China for resources critical for energy technologies. Moreover, the extraction and processing of these necessary inputs can heighten local ecological, political, and justice tensions.[73] Interests across the Arctic have also come under greater scrutiny as rapid warming opens up natural resource extraction possibilities, new sea transport routes, emergency response expectations in the event of accidents, and increased military activity, particularly by Russia (Chapter 29).

US Net Import Reliance by Region for Minerals Necessary for Renewable Energy Technology



US renewable energy technologies rely on imports of critical minerals from around the world.

Figure 17.2. Many mineral inputs critical for renewable energy technologies are imported to the United States. This figure illustrates the diversity of location, mineral type, application, and scale of import reliance.[74] Adapted from Humphries 2019.[75]

Countries may also leverage climate change mitigation and adaptation policies to gain influence and foster new coalitions. Each country will experience a wide variety of climate-related security concerns that can generate new interests or alter existing interests within bilateral relationships.[50,61] For example, climate change impacts can disrupt global supply chains, such as those for food, energy, and critical minerals.[72] These disruptions affect US national security interests, particularly when occurring in tandem with responses to health, economic, and political crises such as those presented by COVID-19 and the war in Ukraine.

US national security, diplomatic, and development agencies are responding to the national security impacts of climate change and competing with other countries in these engagements.[76,77,78,79] Climate change impacts and responses have implications for defense, diplomacy, and development portfolios, including the climate-altered operational environment, US military and civilian infrastructure in partner countries, and humanitarian response.[49,79,80] Government responses include developing climate mitigation and adaptation plans; adapting operations, assessments, and infrastructure to be more resilient; building adaptive capacity and resilience to reduce future risk; and addressing threats and opportunities with a range of defense, diplomacy, and development approaches.[81,82,83] Within this geopolitical context, countries cooperate and compete and may try to take advantage of climate change impacts to gain influence.[49]

A number of multilateral forums (such as the UN Security Council, UN General Assembly, UN Environment Programme, European Union, North Atlantic Treaty Organization, African Union, and Organization for Security and Co-operation in Europe) recognize the interdependent nature of climate change impacts and their implications for national and regional security and have initiated collaborative responses to address transboundary risks.

Defense, diplomatic, and development institutions face increasing operations and emergency response expectations, often arising in new regions that are geopolitically relevant for US interests, as well as increasing requests for humanitarian support worldwide.[76,84] To ensure continuity of operations around the world, adaptation measures ensuring reliable and functional host country infrastructure and services at risk from climate change are a priority for US federal agencies. With international partners, the US Government is increasingly addressing climate-related risks to US national security through a wide range of responses. Assessing and responding to climate-related national security risks relies on the exchange of quality-assured information across global, regional, national, and local scales (see Box 17.1).

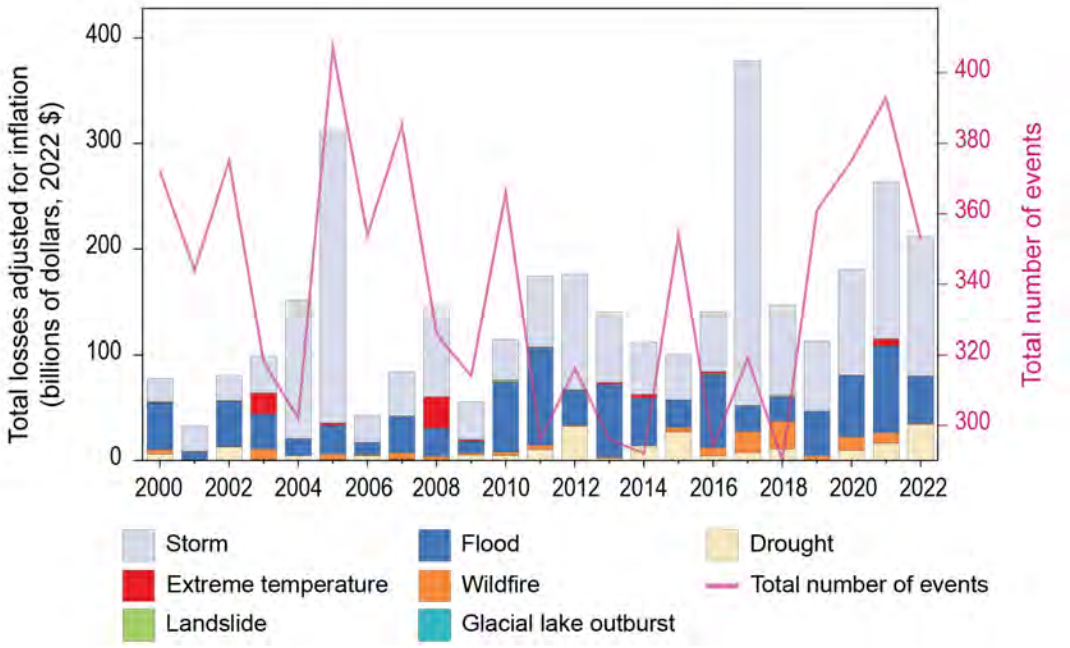
Key Message 17.3

Climate Change Presents Risks and Opportunities for US Economics, Trade, and Investments

The physical impacts of climate change are increasingly affecting global and regional economic growth (*very likely*, *high confidence*). These impacts have important implications for US economic, trade, and investment interests *(likely*, *medium confidence*). Global mitigation and adaptation responses by governments and businesses will likewise impact US economic interests, presenting both risks and potential opportunities for the US economy (*likely*, *medium confidence*). Public- and private-sector institutional, regulatory, financial, and market-based frameworks for climate mitigation and adaptation will influence these risks and opportunities (*likely*, *medium confidence*).

The impacts of climate change on global ecosystems, agriculture, human settlements, infrastructure, health, and migration translate into economic impacts that vary across regions and countries, as well as the extent to which effective adaptation measures are undertaken (Ch. 19).[2,85,86] Losses from climate-influenced disasters are globally widespread and growing, including from a wider range of climate-related events, such as wildfires and floods (Figure 17.3).[87,88,89] Although climate change has played a significant role in these trends, consensus is lacking on the extent to which increased losses are attributable to climate change versus other factors.[90,91]

Climate-Related Disasters and Economic Losses



This figure shows global trends in the number, growing costs, and increasing diversity of types of climate-related natural disasters since 2000.

Figure 17.3. The total global losses associated with climate-related disasters have risen over the last two decades, with growing diversity in the types of climate-related events that lead to disasters (e.g., drought, wildfires, floods) and some annual spikes in storm-related losses. There is little correlation between losses and total number of disasters (suggesting increased losses may derive from increasing severity of disasters, increased value of assets, reporting discrepancies, or a combination of these). Figure credit: DOI, Winrock International, NOAA NCEI, and CISESS NC.

In addition to acute impacts, slow-onset climate impacts such as biodiversity loss and the effects of rising temperatures on health and agriculture in vulnerable regions, as well as nonlinear climate risks (tipping points), will affect economic growth.[92,93] A growing body of literature identifies sea level rise (SLR) as a key driver of economic impacts from climate change, with one study estimating global economy-wide GDP losses as high as 4% by 2100 from SLR-related coastal flooding if no adaptation measures are undertaken.[94]

Climate change impacts beyond US borders expose US economic, trade, and investment interests to risk because these interests are highly integrated in the global economy (Focus on Risks to Supply Chains; Ch. 19). For example, US foreign direct investment overseas and the value of exports and imports reached record levels in 2022.[95,96,97]

Although research relating climate change impacts outside of the US to direct impacts on US trade and investment interests is sparse, analyses suggest several risks to which US overseas investments and trade will be exposed, such as reduced asset values, greater risks of loan default, disincentives for new investments, and trade implications. For example, vulnerable countries face prolonged economic disruption from climate-related disasters, including loss of income and consumption and a higher risk of sovereign debt default.[98,99] Economic shocks in foreign countries are expected to reduce US agricultural exports, production, and farm income (Ch. 11).[100] According to one study, global temperature increases of 3.6°–5.76°F

(2.0°–3.2°C) would reduce midcentury GDP in the US, Canada, and the United Kingdom by 6%–9%, compared to growth without climate change.[101]

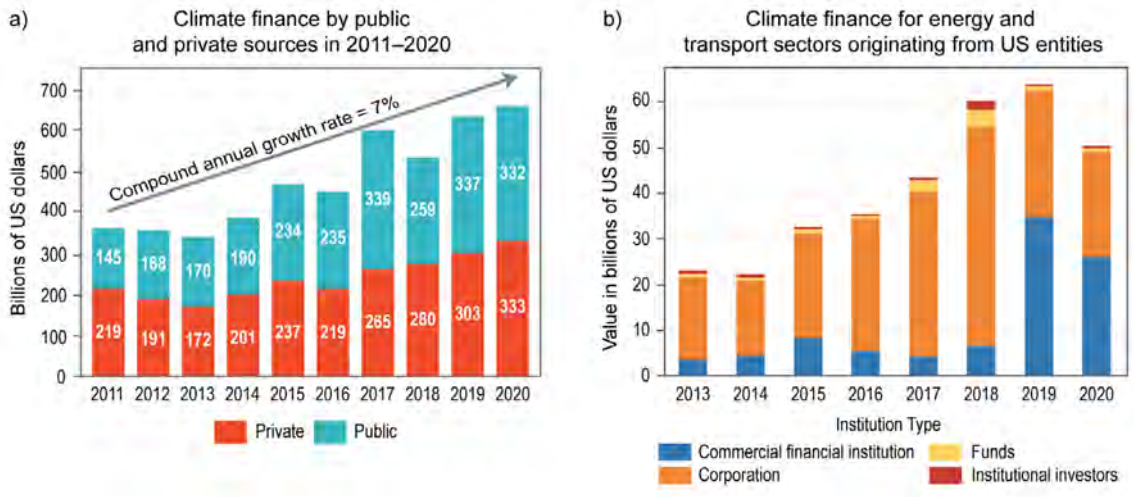
Global climate responses, including policy choices and market responses, present both risks and opportunities for US economic interests as other countries transition toward low-emissions, climate-resilient economies.[86,102] Transition risks include potential job losses, stranded assets, energy price increases, and potential negative impacts on the global financial system.[103] Adaptation responses that restrict development in risk-prone areas could limit options for US investors or leave existing assets exposed.[104]

The global transition, including increased global financing for mitigation and adaptation (Figure 17.4), will also generate innovation, trade, and investment opportunities for US firms (Ch. 19).[105,106,107] Opportunities for innovation and investment include low-carbon energy and carbon capture; transport and infrastructure; adaptation technologies in water, agriculture, health, and other sectors; resilient supply chains; and climate services.[108]

Governments and financial institutions are increasingly using blended finance, green bonds (fixed-income debt instruments that enable investments in climate change mitigation and adaptation), guarantees, and grants to unlock private-sector climate-related investment, including in areas such as land use, reforestation, and adaptation.[109,110] Multistakeholder partnerships are also harnessing market forces to reduce emissions, such as by encouraging deforestation-free commodity supply chains.[111] Workforce development and youth engagement programs are being implemented to prepare economies for the transition to climate-resilient development.[112,113]

Evolving regulatory and market frameworks and financing are important enabling conditions that will influence the effectiveness of global climate responses—including in achieving Paris Agreement climate mitigation and adaptation goals—and their impact on US economic interests.[108,114,115,116] Total global financing for climate mitigation and adaptation (Figure 17.4a) grew steadily from 2011–2020 but slowed in the years just prior to the pandemic and falls short of estimated needs to meet Paris Agreement goals and avoid the worst impacts of climate change.[117] Private-sector contributions increased between 2011 and 2020, although more slowly than public-sector contributions. Adaptation finance grew nearly three times faster than mitigation; however, methodologies for tracking adaptation finance are less developed than mitigation finance and subject to data gaps, particularly from the private sector.[118] While important caveats apply (see Figure 17.4 metadata), US investments in the energy and transport sectors have grown steadily between 2013 and 2020, largely tracking overall global climate finance increases, including in these sectors, albeit more concentrated on domestic US rather than overseas investments (Figure 17.4b).[118]

Climate Finance



Public and private contributions to global climate finance are increasing but not at the pace necessary to avoid the worst impacts of climate change.

Figure 17.4. (**a**) The public and private sectors provided $4.8 trillion in climate finance in total between 2011 and 2020, with the private sector responsible for about half. (**b**) Data on private finance flows originating from the US are most comprehensive for the energy and transport sectors. Figure credits: (a) adapted from Naran et al. 2022[118] [CC BY-NC-SA 4.0]; (b) DOI, Winrock International, and Climate Policy Initiative.

Regulations and economic incentives supporting mitigation and adaptation, carbon markets, climate-related innovation, reduced deforestation, subsidy reform, and climate-related risk disclosure can spur companies, investors, and others to address climate risk (Ch. 19). Public sector policies and frameworks to incentivize greater ambition on mitigation include the 2022 US Inflation Reduction Act (IRA) and the EU's Carbon Border Adjustment Mechanism (CBAM), adopted in May 2023. The CBAM may impose costs for US exporters to Europe and spark retaliatory measures by others, with spillover impacts for US exporters to other regions.[119,120] Although domestically oriented, the IRA may spur investment by US companies in renewable energy and other technologies that could be applied to international markets.

Investors and companies increasingly view climate change mitigation as a business necessity and an opportunity.[108,121,122,123] From November 2020 to November 2021, the number of companies worldwide committing to reducing their carbon footprint to "net zero" through emissions reductions, carbon capture, and emissions offsets by 2050 or sooner had grown from 30 to more than 450, and the value of assets represented multiplied 26 times.[124]

The value of global carbon offset trading quadrupled from 2018 to 2021.[125] The Paris Agreement Article 6 rule book, adopted in 2021, creates global norms for government carbon trading and is expected to inform private transactions.[126,127,128] A maturing carbon offset market is projected to grow 15-fold by 2030 and 100-fold by 2050, presenting opportunities for US firms to meet mitigation goals through overseas investments and the potential to generate resources to support local adaptation measures.[129,130,131,132] There remain concerns that carbon trading could shift burdens onto developing countries, vulnerable communities, and future generations.[133,134]

A growing number of investors and asset owners have committed to evaluate and disclose climate risks. As of September 2022, 3,400 organizations from 95 countries have supported the Task Force on Climate-Related Financial Disclosures, representing nearly all economic sectors.[135] Banks, insurance

companies, and pension regulators are focusing on climate-related risks.[136,137,138] The US Securities and Exchange Commission has proposed mandatory climate financial risk disclosure, paralleling similar actions by the United Kingdom and others.[139,140]

Despite growing corporate interest in addressing climate change, implementation lags behind commitments to climate risk disclosure and net-zero goals. Pressure is growing to convert these commitments into credible measurable actions, including through science-based targets.[113,141,142,143,144] Small- and medium-sized enterprises may face challenges navigating complex reporting standards, which could impact their competitiveness and access to financing.[145] Increased climate risk disclosure may increase costs and discourage US investment in vulnerable areas.[146]

Despite historic challenges, increased awareness of risks and market opportunities has begun to generate interest in private investment in adaptation. Private-sector adaptation investment has begun to be tracked alongside public climate adaptation finance, although less than $500 million was identified in 2021.[117] Institutional investors have begun to develop frameworks for investing in climate adaptation and resilience opportunities.[147] The Adaptation Solutions Taxonomy, peer-reviewed and released in 2020, identifies companies supporting adaptation and climate resilience solutions.[148] The first private investment fund secured $185 million for climate resilience and adaptation technologies in 2022.[149]

While government regulations, expenditures, and market-driven climate responses are key to creating enabling environments for climate responses, they can also increase corruption risks, which in turn can undermine business efficiency, frustrate the effectiveness of climate responses, and exacerbate insecurity or poor governance.[59,60] Thus, enabling environments to ensure transparent, accountable, and participatory climate responses may impact the balance of risks and opportunities for US businesses and economic interests.[150,151,152]

Key Message 17.4

Climate Change Undermines Sustainable Development

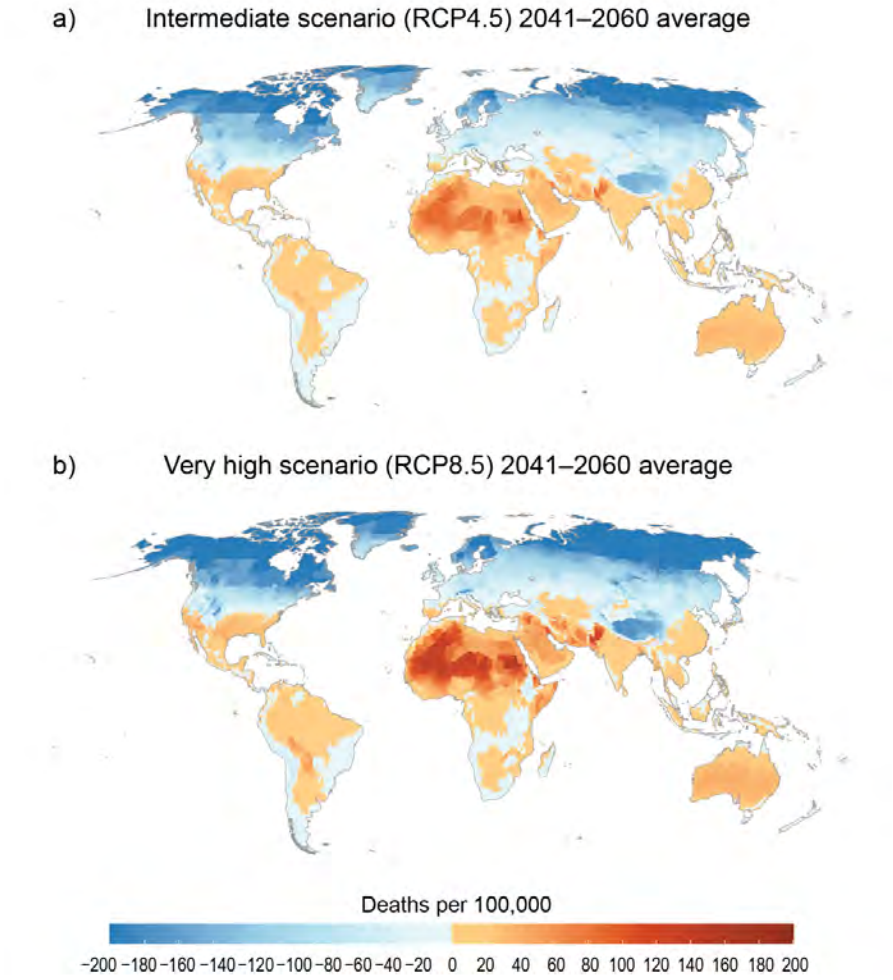
Climate change undermines the world's ability to develop sustainably, reverses development gains, and exacerbates inequities (*very likely*, *high confidence*). Climate finance is increasing, but global flows continue to fall short of needs (*likely*, *high confidence*). Accelerated deployment of adaptation and mitigation action at scale can yield substantial benefits for sustainable development (*likely*, *medium confidence*). Climate action is most effective when co-developed and grounded in equity, local ownership, and inclusive governance (*likely*, *medium confidence*).

The impacts of climate change are globally pervasive, touching all aspects of human, built, and natural systems, including food security, poverty, health, water, infrastructure, and education, among others. Climate change is a risk multiplier in the face of existing development challenges, such as a rapidly growing population base; increased migration, particularly to urban centers, and displacement; increased food insecurity; and rising energy demands. These development challenges are also hampered by reductions in the capacity of natural resources and landscapes to buffer against increased risks, an inability of lifeline services to keep pace with needs, limited economic diversification, low educational levels, and weak institutions to manage these changes.[153] In conjunction with these and other factors (Figures 17.1, 17.2), climate change undermines sustainable development, reversing the significant development gains made in recent decades.[154,155,156,157] These challenges highlight the need to take into account the impacts

of climate in development trajectories in order to inform mitigation and adaptation response to achieve sustainable development.[158,159,160]

Globally, an estimated 26 million people are falling into poverty every year due to extreme weather events such as floods and droughts, and projections point to millions more that could be pushed into poverty by midcentury due to climate change.[153,161] Climate change impacts fall disproportionately on low-income countries and on marginalized and underrepresented populations, which have fewer resources to adapt. Figure 17.5 shows the differential mortality risks from climate change around the world, which results in unequal distribution of risk between and within countries. Limited resources, response capacities, and geophysical and socioeconomic constraints can reduce the feasibility of adaptation.[162,163,164,165] In some contexts, impacts will be beyond the ability of communities to adapt (Ch. 31).[2] This raises equity concerns, particularly given the relatively small greenhouse gas contributions of many low-income populations.[166,167]

Impact of Climate Change on Mortality Rates in 2050



Climate change will exacerbate global inequalities in mortality rates.

Figure 17.5. A warmer world will interact with existing differential capacities, shifting mortality patterns. Even when accounting for future adaptation and rising incomes, mortality will significantly increase in the Global South. The maps show projected changes in mortality due to climate change in 2050 (averaged over 2041–2060) for (**a**) an intermediate scenario (RCP4.5) and (**b**) a very high scenario (RCP8.5). Adapted with permission from Carleton et al. 2020.[168]

Despite growing climate financing, global finance flows continue to fall short of mitigation and adaptation goals and needs.[2,117] To avoid the most dangerous impacts of climate change, annual international climate finance flows in support of adaptation and mitigation efforts would need to increase by 3 to 6 times from current levels by 2030.[2] Even if mitigation finance goals were met, adaptation finance and the resulting percentage of climate finance toward adaptation would need to increase as well.[169] Adaptation costs for developing countries alone are projected to be $140–$300 billion annually by 2030 and $280–$500 billion by 2050 (dollar year not reported), and some estimates go further to propose a doubling or tripling every few years.[107] To date, most adaptation investments have been fragmented, project-based, small-scale, incremental, sector-specific, and more focused on near-term risks and planning.[170] Achieving mitigation and adaptation goals requires alignment of domestic, international, public, and private investment, practices, and business models.[117]

The increasing debt burden many countries incur to manage climate risks and restore economies and livelihoods after extreme events represents a growing obstacle to sustainable development.[153,171] Although large disasters make headlines, globally the cumulative losses from small-scale recurring disasters account for a larger portion of economic losses and erode community resilience.[2] Proactive investments can help safeguard against budget restructuring or reallocations as extreme events become more frequent. For example, investments in early warning systems, flood inundation models, and insurance schemes could have offered protection and limited the long-term effect of the recent floods in Pakistan, where development funds were diverted to disaster response.

Adaptation investments can be affordable, with benefits that far exceed costs not just in terms of financial costs and benefits but also in reduced humanitarian spending, avoided asset losses, and lives and livelihoods saved.[2] The net benefits of investing in mitigation and adaptation include reduced future losses, positive economic outcomes, and social and environmental benefits. Mitigation benefits are expected to exceed costs, even without comprehensive accounting for avoided losses, reduced adaptation needs, and co-benefits, and higher near-term investments are projected to lead to long-term economic gains.[2] The benefits of investing in adaptation across a range of sectors are significant, spanning from $2–$13 for each $1 invested, with some of the higher ranges being associated with investments in infrastructure resilience, early warning and response, and disaster risk management.[172,173,174] Conversely, estimates of the costs of inaction range from a 7% to 14% reduction in global GDP.[101,175]

There is evidence of effective mitigation and adaptation options that are feasible to achieve at scale in specific contexts.[2] Accelerated response to climate change can shift development pathways toward increased sustainable development outcomes despite climate change trajectories. Climate-resilient development efforts are enabled by responses that span policy, diplomacy, public and private investment, and the development and humanitarian assistance domains.[2,176,177,178,179] Increasingly affordable and accessible low-emissions technologies support shifting away from fossil fuels to limit warming.[2] Policy interventions at multiple levels, especially those involving ambitious near-term mitigation targets from current and projected major emitters, can minimize potential for overshooting 1.5°C (2.7°F) warming.[2] Adaptation efforts can reduce disruptions due to shocks and stressors and help countries and people accelerate responsive solutions, aligned with local needs and opportunities, leading to sustainable outcomes, especially for vulnerable populations.[2,180] Internationally, increased coherence and coordination among humanitarian, peace-building, resilience-building, and development can help address convergent risks and opportunities.[181] Participation in international and transboundary climate efforts is shown to result in national and subnational government and civil society action.[169]

Integrated approaches to mitigation and adaptation can further amplify co-benefits of actions.[182] For example, mangrove conservation and restoration, one of many nature-based solutions with mitigation and adaptation outcomes, can minimize the risk of coastal flooding, reduce greenhouse gas emissions, sequester

carbon, and contribute to broader sustainable development benefits related to food security and nutrition, economic prosperity, marine and coastal protection, and natural habitat and biodiversity.[4] Response options also have trade-offs with each other and with various sustainable development goals due to the complex interconnectivity of climate and non-climate risk (Ch. 31). Increased attention to adverse impacts of responses and development pathways can help avoid lock-in of emissions trajectories, maladaptation, and exacerbated inequalities.[2] Further, global momentum and evidence are growing on approaches to accelerate transformative climate actions that embed systems thinking and innovation to facilitate more resilient development pathways.[183,184,185]

Inclusive governance favoring locally led, collaboratively developed responses can strengthen the potential for enabling effective and equitable climate-resilient development outcomes at scale.[26,185] Meaningful engagement of affected groups (including those historically underrepresented and/or marginalized) and the co-development of information and solutions build capacity and increase support for long-term sustainable and equitable response outcomes (KMs 31.1, 32.2).[186,187] Decision-relevant information, and the capacity to use it in novel ways, underpins effective responses.[188,189,190] This information may be global or local and derived from diverse knowledge sources, including the scientific community as well as Traditional Knowledge. Governance and decision-making processes that integrate climate into substantial development efforts and account for the above factors can minimize trade-offs and adverse impacts and result in climate action that advances US interests in broader sustainable development outcomes.[185]

Traceable Accounts

Process Description

This chapter focuses on the implications of international impacts of climate change on US interests. It does not address or summarize all international impacts of climate change. The topics in the chapter—interdependent climate-related risks; national security; economics, investment, and trade; sustainable development; and climate services—were selected because they represent critical interests that are being affected by climate impacts outside of US borders. Climate effects to these interest areas are context specific and are pervasive across the world. The chapter is limited in terms of providing specific detail due primarily to space constraints and limited literature that specifically addresses climate impacts to US interests.

The authors agree that this points to the lack of a sufficiently timely, policy-oriented, and geographically detailed US Government scientific assessment of climate change outside the US. In addition, current literature does not adequately address or provide evidence on the wide range of response options that could be taken to mitigate impacts. Therefore, US national security and international policymakers and analysts must rely on IPCC assessments, existing academic literature, in-house analysis, or ad hoc contracted studies, which are suboptimal or potentially inconsistent.

Chapter leadership sought an author team that could bring diverse experience, expertise, and perspectives. Care was taken to ensure that the team included both early-career and senior professionals from across government, academia, and the private sector who came from varying geographic areas and personal backgrounds. The authors were selected from the list of individuals who responded to the Federal Register Notice or otherwise directly contacted the US Global Change Research Program (USGCRP) to volunteer. Technical contributors were onboarded to conduct an extensive literature review to further identify any dissensions and help reconcile different inputs. Technical contributors also supported design and development of selected figures. The writing team engaged in conference calls starting in September 2021, and calls continued on a regular basis to discuss content, writing, and technical and logistical issues related to the chapter. The NOAA Technical Support Unit staff joined some of these regular conference calls. Subsets of chapter authors also held conference calls on literature, content, and writing on different sections of the chapter.

Public feedback was sought via Federal Register Notices and a public engagement workshop. During the workshop, the USGCRP and chapter authors shared information about the progress to date of the chapter and sought input from stakeholders to help inform further development of the chapter, as well as to raise general awareness of the process and timeline for the Fifth National Climate Assessment (NCA5).

Key Message 17.1

Interdependent, Systemic Climate-Related Risks Increasingly Affect US Interests

Description of Evidence Base

The literature base on climate change and systemic, interdependent risk has grown significantly since the publication of the Fourth National Climate Assessment (NCA4) in 2018, which looked into transboundary climate risk—that is, how climate impacts in neighboring countries affect US interests. However, the literature on global systemic risks cannot yet be considered expansive; it has evolved from a focus on the

financial sector and has more recently increased—not as a result of climate shocks but rather due to recent supply chain disruptions and the observed ripple effects of COVID-19, which put that interconnectivity into stark relief. According to Li et al. (2021)[19] and Simpson (2021),[20] the existing literature highlights the importance of climate change as a driver of systemic risk, but there is a gap in understanding in terms of the interactions and dynamics that generate risk, the methods to support risk assessment, and the design of adaptation and mitigation responses to address complex risk. There is a lack of evidence surrounding the effectiveness of emerging systems- and scenarios-based approaches that are being designed and implemented to address complex, interdependent risk.[40,46]

Major Uncertainties and Research Gaps

The literature is evolving from predominantly sector- (e.g., water security, food security) or domain-based (e.g., urban areas) risk assessment toward consideration of complex, interdependent systems that can result in compounding and cascading climate impacts.

There is little available literature that focuses on broad and cascading impacts of interconnected/interdependent climate risks in relation to compounding and cascading effects on multiple US interests. Nor is there a literature base that assesses the performance of approaches and measures to address systemic, interdependent risk.

Description of Confidence and Likelihood

There is *high confidence* and it is *likely* that in a globally connected world, climate change impacts on US interests are multifaceted, interconnected, and frequently exacerbated by social unrest and environmental degradation. These interconnections and their ripple effects are well documented.

There is *high confidence* and it is *likely* that the scale and speed of climate-related impacts to US interests are expected to increase, due in part to underlying interdependencies and to the projected intensification of climate change. It is unequivocal that climate change is intensifying and that it will result in increased impacts across systems and value chains.

There is *high confidence* and it is *likely* that emerging systems- and scenarios-based approaches to integrative planning are being applied to account for interdependencies and competing priorities. Although these approaches have been developed and are being applied to identify risks and responses, the literature surrounding their effectiveness is less advanced.

Key Message 17.2

Climate Change Exacerbates Risks to National Security

Description of Evidence Base

The literature base on climate change and national security has grown significantly since NCA4, as well as in the approximately 15 years since it became a more prominent focus for scholars and practitioners.[48,53] Given the significant diversity of topics and regions considered for links between climate change and national security, the literature is evolving and cannot yet be considered expansive. Some research questions for which the literature was limited and contested during the NCA4 review period have since seen significant additions and greater agreement among findings, including collaborative research efforts among large groups of scholars. An example of this convergence of findings in recent years involves questions around causal links between select climate impacts and the onset of conflict.[52] Literature on other research questions, such as causal links between climate responses and conflict, is less advanced and more deductive,

often based on historic responses in related issue areas. The number and diversity of US government responses to climate change and national security actions have expanded since the NCA4 review.[49,50]

Major Uncertainties and Research Gaps

Given the diversity of potential research topics connected to climate change and national security, a number of issue areas and geographies have limited literature using diverse methods. In some cases, data remain limited in scales and locations, which constrains the types of methods that can be utilized. In other instances, the institutional responses to climate change that may have national security implications remain in early stages and therefore do not present an evidence base that could generate research findings with the highest levels of confidence.

Description of Confidence and Likelihood

There is *high confidence* and it is *likely* that climate change can be a contributing factor to political and social instability and in some instances conflict. There is *high confidence* and it is *very likely* that climate change increasingly impacts the operations and missions of defense, diplomacy, and development agencies and departments critical to US national security. There is *high confidence* and it is *very likely* that defense, diplomacy, and development agencies and departments are increasingly addressing climate impacts and responses across the government. These confidence levels are based on an in-depth review of a robust body of literature drawn from numerous disciplines, as well as a growing set of US Government and international policies, programs, and assessments.

Key Message 17.3

Climate Change Presents Risks and Opportunities for US Economics, Trade, and Investments

Description of Evidence Base

There is significant research on global and regional impacts of acute and chronic climate-mediated risks.[2] There is an emerging body of literature that analyzes economic impacts of these risks on global and regional economies.[85,86] However, studies that draw conclusions regarding macro-level economic impacts of climate change (e.g., Swiss Re 2021[101]) require assumptions regarding the cost of uncertainty that would benefit from peer review and more analysis. The most granular data on the costs of physical climate impacts pertain to acute risks, such as climate-mediated disasters, rather than chronic risks. However, there is debate among scholars on the degree to which the economic effects of acute events are attributable to climate change.[90,91]

Figure 17.3 reflects data reported to EM-DAT, the International Disaster Database on disaster-related events, types, and costs.[191] The categorization of data within this database is dependent on how events are reported, and there may be some discrepancies in how specific events and associated losses are characterized by reporters. For example, EM-DAT captures events and quantifies losses for storm events (including tropical, extratropical, and convective storms) as well as floods (including coastal, riverine, flash, and ice-jam floods). However, EM-DAT does not provide guidance to data reporters for distinguishing flood events from storm events; as a result, damages from floods caused by storm events could potentially be reflected under either "storms" or "floods." However, the purpose of the figure is to show overall trends in event types and damages; the potential for discrepancies in how these events and associated damages are reported in the database is not material to the overall intent of the figure.

A relatively sparse but growing body of literature analyzes economic effects of climate change on sectors or topics in which US economic interests are highly embedded, such as sovereign lending,[98,99]

agriculture,[100,192,193,194] and migration.[195] These studies offer insights from which expected economic impacts on US economics, trade, and investment may be inferred; however, they generally fall short of attempting to quantify isolated impacts to US economic interests.

A growing body of literature from think tanks, consultants, multistakeholder organizations, and institutional sources provides empirical evidence of trends and practices regarding economic risks and opportunities and participation of private-sector interests in climate responses. The literature available in peer-reviewed scientific journals is less extensive than reports and studies available from non-peer-reviewed sources but is growing. Recent literature addresses the impact of corruption on climate responses. However, the most comprehensive and authoritative assessment of corruption risks posed by climate responses derives from a 2011 study.[152]

Major Uncertainties and Research Gaps

Literature estimating the global and regional economic impacts of physical climate risks, as well as of mitigation and adaptation response choices, is evolving. In addition to more granular analysis of these impacts across different risk categories, gaps in the literature include analysis of how economic impacts outside the US spill over into impacts on US economic, trade, and investment interests. Greater exploration of how policy, regulatory, market, and financial enabling environments mitigate or exacerbate economic, trade, and finance impacts—both at the global and regional levels as well as for US interests—would be valuable. The interrelationship of corruption and climate responses is a topic of emerging relevance that would benefit from updated research and analysis.

Description of Confidence and Likelihood

There is *high confidence* and it is *very likely* that the physical impacts of climate change are increasingly affecting economic growth at global and regional levels outside of the United States.

There is less authoritative analysis of how these global and regional economic impacts translate into impacts on US economic, trade, and investment interests. Studies of specific areas of economic impact in which US economic interests are highly embedded suggest *likely* implications for US interests, which can be inferred with *medium confidence*.

Similarly, while it is clear that responses by governments and the private sector to climate change will affect the economic impacts of climate change globally and in specific regions and that these responses are expected to translate into both risks and opportunities for US economic, trade, and investment interests, there is a lack of precise analysis attempting to quantify these effects. Consequently, these impacts are assessed as *likely* and with *medium confidence*.

An important mediator of these impacts is the quality and effectiveness of policy, regulatory, market, and financial frameworks that governments and private institutions develop to enable climate change mitigation and adaptation responses. The impact of these enabling environments on US economic, trade, and investment interests is assessed as *likely* and with *medium confidence*.

These confidence levels are based on empirical observation of trends and developments, supplemented with scholarly analysis and significant data relevant to business practice and sentiment reflected in the copious trade literature.

Key Message 17.4

Climate Change Undermines Sustainable Development

Description of Evidence Base

The literature base on climate change, sustainable development, and disaster risk reduction and recovery has grown since NCA4. The literature base is expansive given the diversity of topics, and it is further evolving. Some research questions where the literature was limited and contested during the NCA4 review period have seen significant additions and greater agreement among findings. An example of this convergence can be found in the improved understanding of the importance of interconnectivity of climate and non-climatic impacts on populations and potential effective response options.[185] There has been an increase in literature on the social and economic impacts of climate change and on the implications for poverty and exacerbating inequality.[153,161] Likewise, increasing evidence not only points to the growing need for climate finance and aligning investments for both mitigation and adaptation but also recognizes that while climate finance is increasing, it is not matching or keeping pace with this need. The evidence base on response options has greatly expanded, and the authors have focused on emerging trends and cross-cutting efforts instead of attempting to represent the vast literature on specific response options within various sectors.

Major Uncertainties and Research Gaps

Given the diversity of potential research topics connected to climate change, sustainable development, and disaster risk reduction and recovery, there is not consistent depth of literature across research topics, geographies, levels (from local to international), and sectors. In some cases, data remain limited in scales and locations, which constrains the types of methods that can be utilized. In other instances, the nature, extent, and effectiveness of responses relative to this section remain in early stages and therefore do not present an evidence base that could generate research findings with the highest levels of confidence. Additionally, the evidence base on the costs and benefits of implementing proactive adaptation strategies is ample but fragmented and very context dependent.

Description of Confidence and Likelihood

There is *high confidence* and it is *very likely* that climate change undermines the world's ability to develop sustainably, reverses development gains, and exacerbates inequities. Climate change is threatening achievability of the 2030 Sustainable Development Goals, and impacts are *very likely* falling disproportionately on poor, marginalized, and underrepresented populations, and on developing countries in particular, raising equity concerns given that these individuals and countries contributed least to climate change.

There is *high confidence* and it is *likely* that climate finance is increasing, but global flows continue to fall short of needs. There is a significant literature base to support the statements that climate finance is growing but not keeping pace with current needs and that proactive investment is more cost effective than reactive investments.

There is less analysis and evidence regarding the benefits of large-scale mitigation and adaptation action at scale, leading to *medium confidence* and an assessment of *likely* that accelerated deployment of adaptation and mitigation action at scale can yield substantial benefits for sustainable development.

There is *medium confidence* and it is *likely* that climate action is most effective when co-developed and grounded in equity, local ownership, and inclusive governance.

Introduction

The Fifth National Climate Assessment assesses the many ways climate change affects people, nature, and infrastructure across the Nation and around the world. The chapters are divided up by sectors and topics, such as water (Ch. 4), food (Ch. 11), economics (Ch. 19), and social justice (Ch. 20). They are also organized by region, from the Northeast (Ch. 21) to Hawai‘i and the US-Affiliated Pacific Islands (Ch. 30).

But in reality, the impacts and risks of climate change unfold across interacting sectors and regions. For example, a forest fire in one region (Ch. 7) can affect air quality (Ch. 14) and human health (Ch. 15) in other regions as well (Chs. 21–30), depending on where winds blow. Further, climate-related hazards interact with multiple stressors that might seem like they have nothing to do with climate change, such as the COVID-19 pandemic, economic recessions, or social inequities. For instance, different households with different levels of wealth can have very different capacities to evacuate in advance of a hurricane or recover if their homes are damaged (Chs. 9, 20, 22, 23).

As a result, if the perspective of only a single sector, topic, or region were considered, many climate impacts might be missed or overlooked. The consequences of climate change would be unexpected and surprising. And at the same time, the prospects for climate responses, whether through adaptation or mitigation, also fundamentally depend on these same interactions across sectors and regions. For example, using water (Ch. 4) for hydropower (Ch. 5) can impact fish in rivers (Ch. 8), as well as water supply for agriculture in rural communities (Ch. 11) and residential use in big cities (Ch. 12). Without considering such types of interactions, climate responses will be less effective, and there could be missed opportunities.

This chapter is about these deep connections inherent to climate impacts, risks, and responses. The chapter considers these interactions and interdependencies across sectors and regions as complex systems that can lead to cascading impacts and sudden failures, as well as sometimes surprising potential for reducing our emissions of heat-trapping gases and preparing for climate risks that can’t be avoided.

The chapter is organized as follows. First, it introduces what we know about complex systems and explains how complex systems—involving interactions across sectors and regions—can lead to climate impacts that happen faster than expected or can limit future options (KM 18.1). Second, the chapter assesses how complex, interacting climate impacts and responses can be most stressful for overburdened communities (KM 18.2). Third, the chapter evaluates how collaborative approaches to generating knowledge about complex systems can lead to better climate responses (KM 18.3). Finally, the chapter considers the degree to which current governance approaches are adequately prepared to handle the complexity of climate change (KM 18.4).

Key Message 18.1

Human–Nature Interconnections Create Unexpected Climate Risks and Opportunities

Human–natural systems are dynamic and complex. Interconnected networks of people, infrastructure, commodities, goods, and services influence changing climate risks and are increasingly vulnerable to their impacts (*high confidence*). The vulnerabilities in these networks, and their effects on human–natural systems, strongly depend on human responses and other compounding stressors (*high confidence*). Decision-makers seeking to reduce climate change risks have to navigate diverse and sometimes competing objectives and perspectives across many actors, institutions, and geographic scales while reconciling deep uncertainties and limits to predictability (*high confidence*).

In a changing climate, interconnections among human and natural systems give rise to both successes and failures. For example, power systems can fail if exposed to extreme wind or extreme heat (KM 5.2). When they fail, transportation, water and wastewater treatment, telecommunications, health services, and many other economic activities are also disrupted (KM 19.3).[1,2] The interactions among people, systems (e.g., networks, nature), and sectors thereby transmit opportunities and risks from one to another (e.g., KM 27.4), such as from the power system to the transportation system. These interactions lead to new risks and can both increase and limit existing threats.[3,4,5,6] Figure 18.1 shows six interconnected and overlapping features of human–natural systems; each of these features contributes to the complexity of the systems and influences the effectiveness of climate mitigation and adaptation actions. Box 18.1 illustrates these types of interactions through a specific example, data centers.

Climate change makes the existing interconnections between human and natural systems more important for two reasons. First, many human and natural systems have conditions in which a small shock or change can produce very large impacts, but these conditions are rarely known in advance.[7] For example, the winter storm in Texas in February 2021 was a relatively brief 10-day shock of extreme cold weather, but it caused cascading failures across many sectors (e.g., energy, water, health), as well as fatalities and long-lived economic impacts for the region and for individuals.[8] There is evidence that warming in the polar north can increase the potential for these types of winter storm shocks in the US.[9] Second, climate change puts natural systems into fundamentally new conditions, so there is a greater chance of experiencing these large potentially negative impacts. Climate change–driven aridification of the American Southwest is an example of a fundamental change that has resulted in more persistent and severe heat as well as drought extremes. The consequences of this fundamental change are complex, increasing the potential for compounding and cascading impacts. These effects include simultaneous increases in the potential risks for human health, disruptions to critical transportation services, stress on power systems, and water scarcity conflicts across regions and sectors.[10,11] The overall risk of bad outcomes increases, and the sources of risk are more complex. There has been substantial progress in the study of complex, adaptive human–natural systems.[3,12,13,14,15,16,17,18] Innovations across many disciplines are helping to address interconnected risks.[19,20,21,22,23,24,25,26] Further, climate mitigation and adaptation actions depend on one another and interact. They both require resilience to intensifying and increasingly complex mixtures of future influences, shocks, and hazards. Figure 18.1 shows how these future influences can be climate-related hazards, such as floods, droughts, or wildfires; environmental shifts, such as changes in forest composition; or social trends or disruptions, such as from changes in economies, political contexts, cultures, or disease.[2,5,12,16,22,23,26,27,28,29] Mitigation and adaptation involve major changes to human–natural systems with global to local implications (KMs 31.1, 32.5). They can create fundamental shifts in supply chains, consumption patterns, technologies,

and competition over constrained natural resources (also see Focus on Risks to Supply Chains).[13,27,30,31,32,33,34] These changes are expected to continue to have disproportionate impacts on exposed populations and ecosystems (KMs 4.2, 5.2, 8.3, 9.3, 15.2).

There are therefore trade-offs, linked benefits, and dependencies among energy transitions, adaptation actions, and sustainability goals (KMs 17.4, 25.4, 31.3, 32.2).[12,15,19,22,28,35,36,37,38,39,40] For example, an increased supply of clean energy helps power air-conditioning to keep homes cool under intensifying heat while also ensuring that this increased energy usage does not cause emissions of heat-trapping gases. This situation also has implications for social equity and justice, as poverty reduction and improved energy security are needed for all households to afford adequate air-conditioning. These interactions demonstrate the importance of accounting for diverse forms of knowledge, social and institutional power dynamics, and justice in navigating risks, challenges, and benefits of interventions and policies (Figure 18.1; KMs 16.3, 17.4, 20.1, 31.3).[31,41,42,43] Recent advances offer promise for assessing risk–benefit trade-offs, interconnections, and sequences of action or inaction across scales.[44,45,46,47] However, rapidly changing human systems, their multisectoral dynamics, and their interconnections with natural systems create deeply uncertain futures. Many futures are possible, and there is disagreement on how probable they are or how they may shape different human–natural systems' responses. Therefore, significant challenges remain for measuring risk–benefit trade-offs when evaluating potential actions.[48,49,50,51]

Recognition of these deep uncertainties and the difficulties in predicting complex interconnections among human and natural systems over long time periods has led to an approach called exploratory systems modeling.[52,53,54] This approach considers diverse scientific perspectives and uses scenarios to better understand a wide array of possible future outcomes. For example, scenarios can examine the consequences of extreme weather conditions that have never previously happened but may happen under a future climate. The approach aims to discover what future conditions, actions, and outcomes are the most consequential.[45,47,55,56,57] Capital investments associated with new energy sources and climate adaptation are both expensive and long-lived. Exploratory modeling of benefits and impacts of these investments can help avoid the unintended amplification of risks and increase future resilience. Exploratory modeling can support adaptation planning by providing a wider array of futures, such as for coastal systems under sea level rise,[58] and by more clearly identifying responses as they occur among interconnected, complex human and natural systems.

Interacting and Overlapping Features of Human–Natural Systems

Climate-related experiences and actions connect with many other activities and contexts.

Figure 18.1. Interacting and overlapping features of human–natural systems shape actors' capacities to respond to climate change. The effectiveness of decisions and actions—taken or not (teal center of the figure)—is shaped by multiple other features (outer rings). Ways of knowing (light blue ring), such as local, Indigenous, or scientific knowledge, are a foundation that determines how climate risks and responses are perceived and understood. Moving outward, interactions across sectors (e.g., water and energy) and geographic scales (e.g., from local neighborhoods to the Nation as a whole) determine risks and responses under both climate-related hazards (e.g., flooding, drought, wildfire, and heat) and non-climate influences (e.g., social inequities and cultures). Ultimately, these features together define the complexity inherent to climate risks and responses. Adapted from Brelsford and Jones 2021.[59]

Box 18.1. Data Centers Create a Critical New Interconnection Between Energy, Water, and the Economy

Data centers are buildings that house large computer systems that support online activities and much of the US economy. There has been rapid growth in the number and size of data centers as the national economy has shifted toward digital communication and activities. Although water and energy use of individual data centers can be difficult to measure precisely,[60] their water and energy footprint is large—accounting for 1.8% of total US electricity usage and 510 million cubic meters of water in 2018—and is an increasing focus of research.[61,62,63] The siting of data centers is a complex problem, influenced by local and state government incentives as well as by land, energy, and water availability to support cooling, such as in climates favoring evaporative cooling. The future demand for data centers, together with their needs for water and energy and their influence on linked water–energy–land systems, will vary considerably geographically.[62] Given that data centers depend on both water and energy and are themselves infrastructure critical for the functioning of the economy, data centers create a new interconnection between energy, water, and the economy.

In the western US, where arid climates are favorable to the evaporative cooling often sought out for data center operations, water and land are inextricably linked through prior-appropriation water law (KM 28.1).[64] As a result, securing adequate supplies of water to support data center demands can become a complex and potentially contentious exercise in acquiring agricultural land and fallowing it, a process that is dependent on state laws governing the transfer of water rights. Moreover, the increasing potential for large-scale, long-term droughts in the western US could lead to unanticipated events (KMs 4.1, 6.1, 28.3). For example, increasingly heavy base-load water consumers such as data centers may make the water system less able to adapt to drought through short-term conservation. Increasing attention to the environmental footprints of new data center projects in the western US potentially signals a new interconnection and potential point of conflict between economic sectors (KM 6.3), such as technological industries versus agriculture.

Key Message 18.2

Complex Climate Impacts and Responses Further Burden Frontline Communities

Compounding and cascading interactions among sectors, hazards, and geographies magnify the impact of climate change and societal responses for already-overburdened groups (*high confidence*). However, social vulnerability assessments tend to evaluate risks and impacts by sector, hazard, or jurisdiction, and most complex-systems models do not yet account for social and political dynamics (*high confidence*). Data about how complex systems affect frontline communities under climate change are severely lacking, especially for hard-to-reach populations, and this can lead to disproportionate risks and impacts for these groups (*high confidence*).

The complex systems described in KM 18.1 can create cascading and compounding climate impacts that particularly affect people and communities with little flexibility to absorb additional stress. This includes smaller and more rural communities, lower-income households, racialized minorities, people with health conditions and disabilities, pregnant people, caregivers, young children, and older adults (KMs 4.2, 15.2, 16.2).[18,65,66,67,68,69,70,71] The combination of complex societal factors (Figure 18.1) with people's multiple roles and identities shapes their lived experiences of multiple shocks and stressors (Figure 18.2).[72,73,74] It is not an accident that access to land, housing, infrastructure, food, and water in the US is highly unequal.[67,75] Within a context of institutionalized inequality and uneven access to safe housing and quality infrastructure, new and conflicting private- and public-sector responses to complex climatic and non-climate events often reinforce existing inequities.[18] At the same time, each person carries multiple identities and plays multiple roles, creating intersectional vulnerabilities that can intensify direct impacts of climate change and indirect impacts of climate actions by more privileged groups. For instance, in rural Alaska, climate change is rendering more difficult the lives of Iñupiat women as they care for multiple generations, maintain land-based food and cultural systems, and endure gender-based violence,[76] while young, single men working in the oil and gas industry are experiencing the energy transition very differently.

Increased exposure to flooding provides an example of how compounding and cascading interactions and intersectional vulnerabilities can amplify harm in already-burdened communities. Legacies of inequitable access to residential home loans, municipal incorporation to isolate wealth in suburbs, and infrastructure investments that privileged certain neighborhoods and municipalities over others have concentrated low-income people, African Americans, and other frontline communities in places with high flood risk.[77,78,79,80] Federal flood risk response programs privilege predominantly White and wealthier communities by giving them more funding for levees or seawalls.[81] These measures worsen downstream or down-coast flooding in places that might not be able to afford such infrastructure.[80] Federal programs also disproportionately fund predominantly White communities to voluntarily relocate from floodplains (Figure 20.3),[82,83,84] while low-income people, including renters, receive less assistance and have to move farther away to places with fewer amenities.[85] Box 18.2 shows a different example of how cascading and compounding events can worsen long-standing inequities. It discusses how a wildfire exacerbated social conflict over land, housing, and infrastructure in California. Accordingly, people's cumulative vulnerability can be understood and addressed only through multiple scales of analysis (e.g., Turek-Hankins et al. 2020[86]) and through integrated strategies for housing, planning, social services, lending, and racial justice.

Models of how climate impacts affect complex systems and how societies can respond usually do not account for people's diverse roles, identities, and lived experiences nor the social, political, and governance

characteristics of decision-making.[3,87,88,89,90] For example, political polarization, in addition to structural inequities, increasingly shapes individual and government responses to disasters and long-term planning.[91,92] This can lead to a patchwork of mitigation and adaptation efforts across a region, which can weaken overall system function.[93,94,95] Data gaps exacerbate the modeling uncertainties described in Key Message 18.1, especially for smaller, less studied urban, suburban, and rural areas and Indigenous communities (KMs 11.3, 16.2).[69,96,97] Research on the linkages between places, such as how impacts on agriculture systems affect urban food security, migration, and housing demand, is also limited (KM 11.2).[98] The absence of research on the lived experiences, climate impacts and risks, and implementation outcomes for overburdened communities often leads to their underrepresentation in decision-making.[99] Accounting for people's diverse roles and identities, modeling social and political responses to climate change, and improving data availability can improve the modeling of complex systems and the inclusivity of decision-making tools.

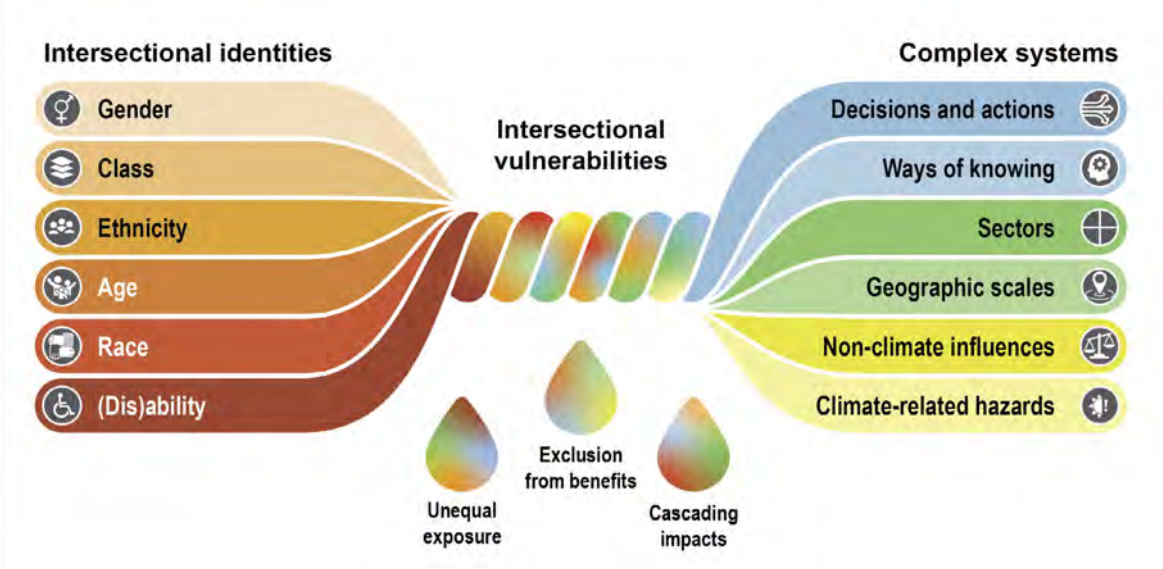
Box 18.2. Wildfire and COVID-19 Lead to Compounding and Cascading Impacts over Time

Disasters can trigger compounding and cascading effects on displacement. While research has focused on flood-driven displacement in the US,[100,101] other hazards are also intensifying migration pressures (see Figure 20.5). The Camp Fire, which devastated Paradise and surrounding Northern California communities in November 2018, illustrates how climate migration can trigger cascading impacts in places receiving displaced persons (KM 28.4). The Camp Fire killed 85 people, destroyed roughly 19,000 buildings, and displaced more than 50,000 people.[102,103] Many evacuees fled to the nearby city of Chico, which swelled from 93,000 to more than 111,000 people.[104] Chico Police Chief Michael O'Brien said, "You normally would have a decade to prepare for such growth. We had about 10 hours."[102]

In-migration increased traffic by 25%, sewage inflows by 16%, and annual sewage treatment costs by more than $725,000 (in 2022 dollars). It also turned Chico into America's hottest real estate market.[102,105] Telecommuters fleeing the Bay Area during the COVID-19 pandemic further fueled Chico's housing affordability crisis. Even before 2018, only 1.5% of housing starts were affordable to people with very low incomes, and the vacancy rate was less than 1%.[106,107] A political action committee stoked fears around skyrocketing housing prices, new homeless encampments, and crime and drugs to shift the city council from predominantly liberal to conservative. Housing policy began to emphasize evictions and criminalizing unsheltered "vagrants," creating significantly greater risks and impacts for Indigenous Peoples, who are disproportionately represented among the unsheltered.[106]

Since then, climate change, worsening air quality due to subsequent wildfire seasons (Figure 14.3), housing unaffordability, the COVID-19 pandemic, and the shift to teleworking are fueling migration in California from rural to urban areas, from smaller to larger cities, and from coastal cities to more affordable and scenic suburban and rural areas.[108,109,110,111] Across the country, most cities' climate vulnerability and risk assessments focus on future climate impacts to current populations without considering disasters taking place elsewhere that could affect their outlook.[112] Models and assessment tools that account for cascading impacts, especially those conducted at regional scales, can help steer or anticipate the effects of climate-exacerbated migration (e.g., Zoraghein and O'Neill 2020[113]). In addition, national and regional climate-migration and housing-resource models can help inform national and local government infrastructure, land use, and housing decisions.

Intersectional Vulnerabilities



Intersecting social and environmental factors privilege some people's ability to respond to climate change.

Figure 18.2. Climate impacts and societal responses exacerbate intersectional vulnerabilities. People's gender, class, ethnicity, age, race, and ability form their intersectional identity (left). Intersectional vulnerabilities emerge when intersectional identities interact with inequities in complex systems, as outlined in Figure 18.1 (right). In the face of climate risks and responses, these intersectional vulnerabilities can result in unequal exposure, exclusion from benefits, and cascading impacts that further impact already-overburdened groups. Societal responses to climate change—including uneven existing resources across municipalities, decisions about where to allocate investments, and noninclusive ways of knowing—can exacerbate existing harms and generate new ones. Adapted with permission from Box TS.4, Figure 1 of Field et al. 2014.[114]

Key Message 18.3

Collaborations Among Diverse Knowledge Holders Improve Responses to Complex Climate Challenges

Responding effectively to complex climate challenges benefits from integrated frameworks and modeling approaches that incorporate diverse types of knowledges suited to specific contexts and needs (*high confidence*). Participatory and collaborative approaches and tools bring together diverse knowledge holders and improve the generation and use of actionable knowledge for complex-systems decision-making (*medium confidence*). These collaborative approaches help navigate complex challenges, such as competing perspectives and knowledge uncertainties, thereby improving climate responses (*low confidence*).

Complex-systems responses to climate change require diverse types of knowledge, incorporating different ways of thinking about climate change and complexity, and often arise through participatory and collaborative processes (KMs 12.4, 20.2, 31.3, 31.4).[115,116] While much research focuses on analyses, modeling, or projections specific to individual sectors, regions, or actors, a richer diversity of information is needed to fully understand complexity.[116,117] Decision-making for complex systems benefits from knowledge

of the interdependence of human–natural systems; the venues where decisions are made; the actors participating and impacted by decisions, politics and ideologies; and the values, attitudes, and beliefs of people and institutions (Figure 18.3).[117] Such knowledge stems from diverse disciplines as well as interdisciplinary and transdisciplinary endeavors. Interdisciplinary work integrates knowledge from different disciplines, and transdisciplinary approaches often additionally integrate knowledge from researchers and nonacademic partners such as communities or decision-makers.[118,119,120,121,122] For instance, social science and humanities research that examines the distribution of inequities of climate change has helped to highlight the overlapping and often compounding impacts on overburdened groups and can be used to ensure the inclusion of those communities in climate response decision-making (KM 18.2). Transdisciplinary knowledge that draws from both academic and nonacademic actors can help clarify systemic feedbacks and path dependencies that might go unnoticed if viewed from siloed disciplinary perspectives alone (Figures 18.3, 29.16).[123,124] Overall, complex-systems responses necessitate moving beyond traditional siloed knowledge production processes to integrated approaches that include diverse types of knowledge and actors.[125,126,127]

The diverse types of actionable knowledge needed for responding to complex climate risks include data and modeling, decision support tools, case studies, art, and lived experiences (KMs 4.3, 13.2, 17.1; Box 19.1). Different types of knowledge can be critical depending on the context and needs. For instance, qualitative forms of knowledge, such as oral histories or ethnographies, provide rich, place-specific understandings of how complex systems function and how climate-related experiences influence behavior.[128] Narratives and crowdsourced data of extreme events, including how people cope with them, have improved the integration of climate knowledge into social and cultural life.[129] Stories have advanced climate and energy solutions by allowing exploration of the intersection of nature, humanity, and technology.[130]

Integrated frameworks that bring together different knowledge types across various sectoral and regional contexts are essential for holistic analyses of complex systems. For example, recent developments in coupled human–natural systems modeling have not only examined cascading impacts across sectors and scales but have also incorporated the feedback relationships from social and political systems back into the models.[131] The Water Utility Climate Alliance has used a "chain of models" approach to link global climate models (GCMs) to hydrological models and then water utility decision-making tools.[132] Connections between GCMs and urban tree canopy models have supported analysis of heat management strategies across multiple dimensions, including air quality, irrigation demand, and greenhouse gas emissions.[133,134,135] Food–Energy–Water (FEW) systems studies have developed frameworks[126,136] to better understand regional to global dynamics within cross-sectoral FEW systems.[131,137]

These advanced integrated frameworks draw on knowledge that stems not just from academics and researchers, but also from a wide range of experts, including practitioners, decision-makers, and local and Indigenous Peoples.[116,127,138,139,140] There are increasing examples of community and citizen scientists monitoring specific environmental indicators at temporal and spatial scales otherwise infeasible (see Table 12.2).[141,142,143,144] The long-term environmental knowledge and socioecological memory held by Indigenous Peoples has helped to detect, understand, and predict complex changes in climate systems.[138,145] Further, land management approaches based on Indigenous Knowledge have long emphasized flexibility and diversity of resources and serve as successful examples of resilient practices under complex environmental changes (e.g., Box 27.3).[138]

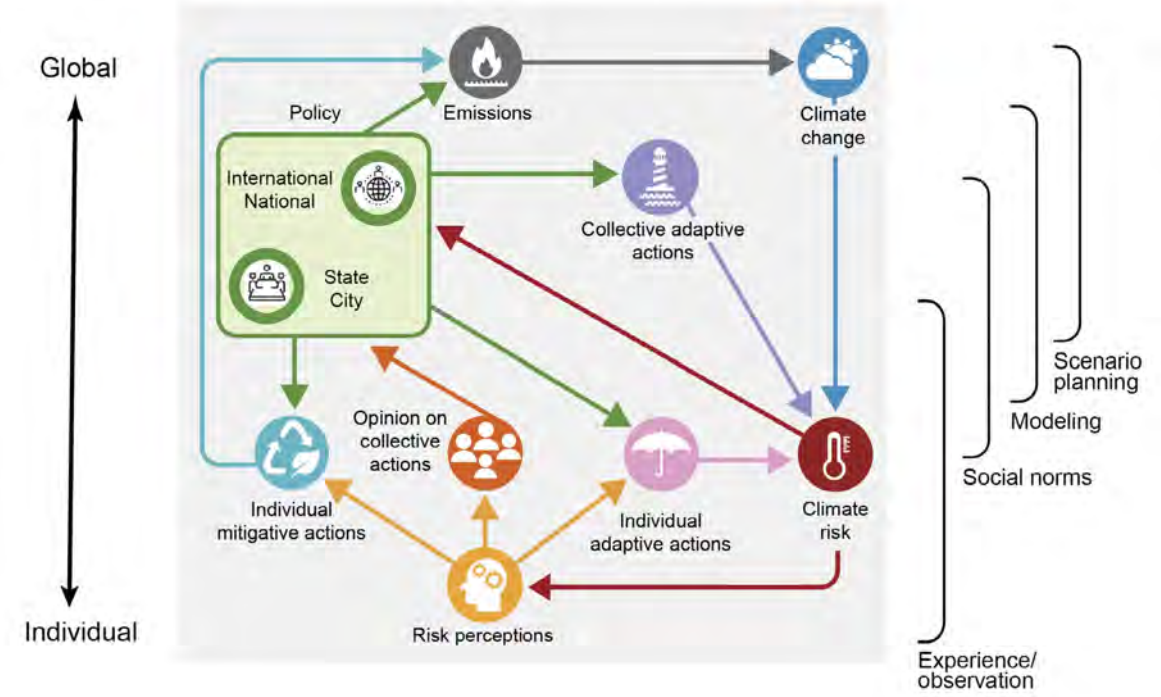
Connecting different knowledge holders and knowledges requires a different type of scientific practice that is more collaborative, participatory, or community-engaged.[116,146,147,148,149] Approaches such as coproduction, which bring together diverse knowledge holders with potential knowledge users, have proven to be successful in developing actionable knowledge for complex systems (Box 18.3; see Key Message 20.2 for more on engaging diverse stakeholders).[150,151,152] Such approaches allow for iteration and deliberation about multiple worldviews and have been effective in improving credibility, relevance, and trust

in knowledge.[115,139,153,154] They also enable better understanding and management of knowledge uncertainties.[154,155,156] For example, participatory modeling of complex socioecological systems has included experience-based practitioner knowledge to improve identification of system boundaries, elicit realistic management alternatives, and increase the decision-relevance of outputs.[21,132,140,157] The county of Los Angeles has used participatory modeling to identify cascading impacts across infrastructural systems, their downstream effects for residents, and key intervention points.[158] Collaborative decision-making under deep uncertainty (DMDU) approaches, such as flexible adaptation pathways, scenario planning, and decision scaling, seek to develop robust climate responses for multiple potential futures rather than planning for a single best-estimate future, and they have also been positively received by decision-makers (see Figure 18.4).[159,160,161] The US National Park Service has used collaborative scenario planning, bringing together natural and cultural resource managers and subject-matter experts, to negotiate social and scientific uncertainties associated with climate change and inform the setting of conservation and resource stewardship goals.[162,163,164,165]

Effectively implementing and sustaining such collaborative processes requires specialized boundary organizations and climate services agencies (Box 18.3).[166,167,168] These boundary agencies facilitate, translate, and mediate engagements between scientists and different actor groups. NOAA's Climate Adaptation Partnerships, USGS's Climate Adaptation Science Centers, USDA's Climate Hubs, and university agricultural extension services have emerged as leading boundary agencies for the production and use of climate information through trust- and partnership-building with various knowledge-holder and user groups.[169,170]

Evaluation of effectiveness and equity is an important aspect of efforts to use climate-relevant knowledge in complex-systems decision-making. While there is increasing evidence that many collaborative approaches (such as coproduction, collaborative scenario planning, and DMDU tools) have been effective in improving the production and use of complex-systems knowledge in decision-making (Box 18.3), there has been limited examination of the long-term outcomes and equity of these processes and tools.[151,152,171] Additionally, the relative advantages and disadvantages of when and where different types of knowledges are most useful is also not well understood.[119,172] Overall, despite preliminary successes, understanding of the transferability, impact, and equity of different collaboratively generated knowledge and tools is still emerging.

Interacting Climate Responses and Knowledges Across Scales



Climate responses, ranging from the individual to global scale, interact with and draw from diverse knowledges.

Figure 18.3. Activities of government at multiple scales (green) affect climate risk (red) via multiple pathways, by decreasing or increasing greenhouse gas emissions (gray) and supporting adaptive (or maladaptive) actions (pink, purple). Moreover, government actions are influenced by the opinion and interests of residents, businesses, and other organizations (orange), and they in turn shape the actions of households and businesses (pink, blue). Interacting actors are nested within multiple spatial scales (left) and also rely on different knowledge sources for decision-making (right). Adapted from Moore et al. 2022.[88]

Box 18.3. Different Forms of Knowledge and Collaboration Across Groups Support Local Adaptation

Governments, businesses, community organizations, and residents in coastal cities have been early implementers of collaborative approaches to create actionable knowledge for complex climate responses (KM 22.1; see also Box 9.1). The Little River Adaptation Action Area in Miami-Dade County, Florida, is one such example of a new flexible planning tool.[173] This area is exposed to flooding worsened by sea level rise, and the challenges can be particularly stark. For example, when high tides and rainfall happen at the same time, septic tanks fail, leading sewage to back up into homes and spill into and contaminate waterways. As one resident described it, "I could live with a little bit of flooding if I knew the water wasn't full of sewage."[173] Systemic drivers of disparities across neighborhoods go back decades, and financial hardship means that households often struggle to reduce risks from flooding, as well as from chronic humid heat in the home.[174] Starting out in 2020, the Little River Adaptation Action Area has three main goals: 1) to use data to inform capital projects reducing climate risks (see also KM 31.5), 2) to support collaborative approaches in which community members' knowledge and experience guide climate solutions (see also KM 31.3), and 3) to break down silos and coordinate responses across governments, households, and the private sector. Implementation of this flexible adaptation tool has been led by resilience staff in the region, including importantly municipal chief resilience officers. Supported by research–practice partnerships such as the Resilient305 Collaborative, the county has enabled community-based implementation of multiple regional climate strategies.[173,175,176,177,178]

The Little River Adaptation Action Area has thereby been able to test out collaborative approaches and improve responses to complex climate challenges. First, the planning effort has been guided by overarching principles such as making residents safer through equitable engagement, fair policies, and direct investments; working with nature; and supporting flexible, integrated climate responses.[173,175,176] These guiding principles create clear signposts for designing and updating the collaborative planning process. Second, community workshops and research–practice networks have supported the use of physical and socioeconomic information and diverse knowledges in exploring locally preferred response strategies with support from state and federal partners, such as septic-to-sewer conversion, expansion of green spaces, and improvement of housing.[174,178,179] Granular, transparent data are being used to understand the distribution of climate and policy impacts such as flood and heat exposure across communities, as well as to understand building, household, and neighborhood characteristics that shape impacts on families. Third, evaluation has been embedded into planning efforts, such as by monitoring investments made and how residents perceive them.[180] These evaluation efforts require commitment and rigor, and they are necessary to understand how effective climate responses are for both climate goals and broader priorities, to identify unexpected benefits, and to support course corrections where needed. Fourth, approaches are expanding to address deeper uncertainties, such as the implications of large amounts of sea level rise and pathways that could help ensure longer-term flexibility where it may be needed.[181]

Key Message 18.4

New Governance Approaches Are Emerging, but Gaps in Practice and Evidence Persist

Climate change presents challenges for managing risks and responses across different levels of government, the private sector, and civil society. Current governance entities and their existing jurisdictional authorities are often unable to resolve conflicts posed by the wide-ranging and unprecedented interactions and complexities of climate risks and more localized compounding stressors (*high confidence*). Local and regional governments have experimented with alternative institutional arrangements, funding mechanisms, and decision coordination (*medium confidence*). Thus far, however, there is only preliminary evidence of their effectiveness (*low confidence*). These pilots and other innovations developed for climate mitigation and adaptation may well present opportunities for replication and broader successes in other locations and different local contexts (*medium confidence*).

Climate responses and management practices are expanding to address complexity in coevolving human–natural systems. The need for science-informed, inclusive decision-making around complex climate risks is immense. The form and quality of governance of individual and interacting systems are shaped by government agencies, civil-sector actors, and private-sector entities.[182] The actors and their roles vary across jurisdictions and are dependent on constitutional authorities, modes of control (e.g., proprietary, regulatory, budgetary), geographic territories, climate-related functions, technical capacities, budgets, access to financial and intellectual resources, and institutional or political power. The current state of these factors depends on institutional legacies and their momentum or inertia in response to changing climate conditions.[183]

There are inherent challenges in governing complex systems in response to climate change (KM 31.3). Relevant jurisdictions tend to be highly defined and siloed despite overlapping social or environmental system interactions.[184] Structural inequities established in past governance institutions are often inextricable from current decision-making processes (KM 20.1). Market failures are sometimes ignored (e.g., disclosure of a property's climate risks) or exacerbated by public policy (e.g., securitizing mortgages for risky properties, paying out insurance claims for repeat losses, or decreasing housing affordability as a result of mitigation efforts). Access to financial and intellectual resources has historically been weak at the local level and highly variable across geographies and urban to rural gradients.[185] Governance of complex systems requires flexibility beyond the formal governance of any one system.[186] Alternative processes for decision-making have been proposed or are in preliminary levels of implementation. These include an increased and explicit reliance on available scientific, engineering, and social-science evidence to inform policy. Iterative, participatory planning and deliberation inclusive of all residents or stakeholders are also possible. Similarly, transparency and accountability in public information and deliberations are increasingly important. Improved coordination strategies between governing entities—adjusting to evolving conditions and improving information—include decentralization and de-siloing in the public sector across agencies or jurisdictions, effectively reorganizing government. Governing entities are also looking at making longer-term commitments in public works and social programming and in longer-term visioning scenarios than their current budgetary and planning terms have traditionally prescribed (KM 12.4). Finally, governing institutions increasingly recognize the distribution of risks, path dependencies, and costs and burdens across communities.[18,187]

The state of evidence on effective governance approaches varies for each characteristic of complex-systems management:

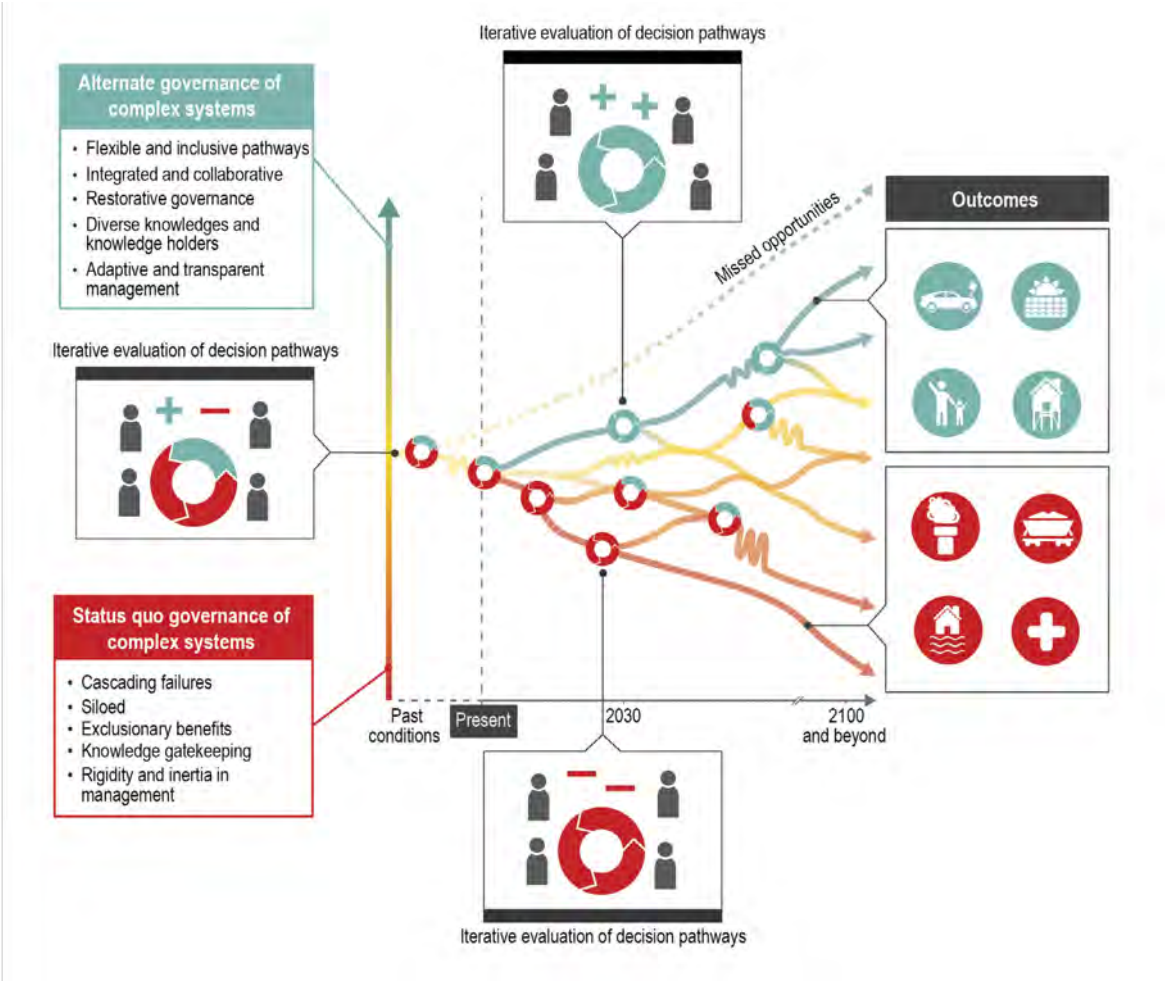
- Complex systems are often characterized by *deep uncertainty*—the presence of systemic structural uncertainties or unknowns without objective probabilities. Climate risks and possible scenarios exacerbate this uncertainty (KM 18.1). Stakeholders such as private-sector interests, public-sector officials, and civil-sector representatives may disagree about the likelihood of future scenarios or consequences of decisions. Effective governance approaches include transparency in system frameworks, integration of contingencies and redundancies, and flexible planning and operations to avoid decisions that are costly or impossible to reverse (Figure 18.4).[188,189,190,191] Actors are already revisiting their crisis management plans to avoid worst-case outcomes and reduce short-term losses.
- Wide-ranging actors within complex systems may have *multiple, often competing objectives* regarding climate actions. In response, effective governance approaches include establishing consistent criteria to evaluate alternative actions, sometimes using consensus-based principles. Inclusive governance, stakeholder consultation, and explicit consideration of multiple criteria are other strategies for addressing cross-system conflicts. However, interactions among actors across overlapping governance structures and systems, combined with strategic behavior for individual decisions, can complicate these processes.[192,193,194,195,196]
- Complex systems are often characterized by *broadly distributed knowledge and power*—with diverse actors controlling knowledge about different parts of the system. Approaches in these polycentric governance systems include processes for data sharing, decision coordination and deliberation, and de-siloing of decision-making in related areas.[117,197,198,199,200,201,202,203,204,205,206,207,208,209,210,211,212] Mechanisms such as market-based approaches can sometimes allow for interaction of diverse actors via price signals, reducing the need for direct, centralized regulations, although these efforts may not account for inequitable financial access and outcomes across stakeholders, particularly overburdened communities.[213,214]
- Governance of complex systems tends to be *geographically and functionally nested*—controlled by multiple jurisdictions such as municipal, state, and federal authorities (Figure 31.4). Coordination across actors in different jurisdictions, together with improved clarity and boundary definitions, can therefore be valuable (Figure 18.3). The primary tools of nested governance structures—that is, regulation, statute, program rules, and coordinated budget transfers from multiple sources—can be negotiated through coordination rather than preemption.[202,215,216,217,218,219,220,221,222,223,224]
- Finally, *feedbacks and path dependencies* are common in complex systems. Choices at one point in time, such as the capacity and siting of physical infrastructure projects, can either expand or limit options later on (Figure 18.4). As a result, the full effects of management actions can be difficult to anticipate, particularly in the longer run. Path dependencies and policy feedbacks can lead to immediate commitments that restrict later change. Effective governance strategies include adaptive management approaches that repeatedly monitor, evaluate, and amend actions, although such governance strategies are not well developed.[225,226,227,228,229,230,231,232,233,234,235]

Overall, there is only preliminary evidence of the effects of alternative governance structures on climate mitigation and adaptation actions or their outcomes. Existing governance structures largely predate contemporary public climate responses and extend histories of US federalism, home rule, privatization, and ad hoc regional collaborations or special districts created in response to temporal needs or crises. These structures have generally not been reconfigured in the face of complex climate challenges, with some exceptions (KM 31.3). The governance structure between the Federal Government and state governments across and between most systems is constitutionally defined. The resulting flows of resources and other forms of assistance are therefore statutorily defined by program authorizations and appropriations. Existing

governance entities such as state government agencies have attempted broad internal coordination among sub-state governments, although adjustments have met with varied success and contested leadership.[236]

There are more examples of alternative governance structures between and within subnational governments. Examples of the former include the cross-state Regional Greenhouse Gas Initiative for climate mitigation actions or the cross-county Southeast Florida Regional Climate Change Compact (Box 18.3) for climate adaptation; these efforts attempt to manage multiple systems across different jurisdictions.[237,238] Other regional coordinating entities have been created across states, counties within states, or cities within counties, including those affiliated with the Alliance of Regional Collaboratives for Climate Adaptation. But these efforts are typically preempted or bounded by the constitutional authorities allowed by the superseding level of government (for example, a state over counties). There is preliminary evidence about the effectiveness of individual climate professionals (e.g., chief resilience officers and related boundary-spanners).[203,239] However, the long-term outcomes from these efforts have not been conclusively measured.[240]

Governance of Complex Systems



Governing complex systems involves pathways of decision-making across time.

Figure 18.4. Adaptively managing complex systems involves a series of choices and actions through time. There are path dependencies shaped by the past and present, opportunities for maintaining flexibility under deep uncertainties, and needs for iterative learning through time. Governance of complex systems is more effective when it is flexible, inclusive, integrated, collaborative, and adaptive. At each decision point in time (circles with arrows), diverse decision-makers evaluate possible solutions available at that time and choose a path forward (people in gray considering benefits and trade-offs of different possible pathways). Given these responses, alternate pathways (red, orange, yellow, and green) may remain possible for the future or become closed off. At each decision point, an important consideration is how actions taken may expand or contract the options available in the future. Adapted with permission from Figure SPM.6 in IPCC 2023.[241]

Traceable Accounts

Process Description

The scope of this chapter was first developed by considering 1) the corresponding chapter in the Fourth National Climate Assessment (NCA4) as a starting point; 2) new emphases on topics relevant to complex systems, intersectoral interactions, and multiple stressors across NCA5; and 3) evolving areas of research and practice. The chapter lead identified important areas of expertise for the author team, including complex-systems methods, engagement methods, and topical expertise (e.g., energy–water–land, coastal, urban). Potential authors were identified from the nominations database, literature searches by the chapter lead and coordinating lead author, and the authors of the NCA4 chapter.

The First Order Draft, Second Order Draft (2OD), Third Order Draft (3OD), and Fourth Order Draft (4OD) were developed from the Zero Order Draft (ZOD) narrative outline through a multistage process. First, feedback on the framework and topics of the chapter was solicited via a public engagement workshop. Discussions focused on the NCA5 chapter framework for complexity, lived experiences, and the management of complex interactions. Second, chapter authors discussed the outline, and a lead author, along with accompanying contributors, was identified for each Key Message, figure, and box. Third, drafting proceeded through iterative processes of full-team and subgroup conversations on the scope and approach for each chapter element, literature reviews, and preparation of text and graphics, as well as identifying emerging assessment findings, areas of overlap across chapter sections, and potential directions for refinement in subsequent drafting stages. Fourth, cross-chapter discussions and the ZOD public review comments were used in the revision of the 2OD. These themes were further prioritized as the chapter was revised in the development of 3OD text and figures, also incorporating the review comments on the 2OD. The 4OD was then developed on the basis of public review and NASEM (National Academies of Sciences, Engineering, and Medicine) comments, with monitoring by the chapter review editor.

Key Message 18.1

Human–Nature Interconnections Create Unexpected Climate Risks and Opportunities

Description of Evidence Base

Key Message 18.1 material draws heavily from the recent assessment conducted in development of the Multisector Dynamics (MSD) vision report,[3] which was an in-depth assessment by a diverse research community directly building from NCA4, as well as recent literature outside the scope of that report. In addition to citing the report itself, Key Message 18.1 directly cites underlying literature from the MSD vision report and other fields such as socio-ecological-technical systems, sociohydrology, complex systems, exploratory modeling, and decision-making under deep uncertainty.[5,12,13,14,15,16,17,18,25,54,56,242] Given this foundation, the Key Message draws from an expansive evidence base, for which agreement in the literature pertains both to areas of agreement across studies and to deep uncertainties that remain.

Figure 18.1 is a combination of new and existing work. The underlying source was a conceptual diagram of complexity in urban systems and the lenses through which it can be organized and understood. Here, the figure has been adapted for complex systems as a whole, pursued through an actor-oriented lens and reflecting the authors' review of figures that explain different aspects of complexity in socioecological systems or coupled human–natural systems under a changing climate.[5,29,243,244,245,246,247,248,249] The MSD vision report executive summary Figure 1 was also a source of inspiration, yet the figure included in this

Assessment centers actors and their capacities to respond. This adjustment reflects increasing recognition of the role of people in complex systems and associated climate risks and responses.

Major Uncertainties and Research Gaps

Major uncertainties are explicitly acknowledged in the discussion of deep uncertainties inherent to complex systems. Based on the available literature, we provide assessment of emerging approaches relevant to complex systems under such uncertainties. There are deep uncertainties in predicting complex interconnections among human and natural systems over long time periods, which are particularly exacerbated by a lack of human systems research that focuses on the interactions between human and natural systems.[12,14,22] Exploratory systems modeling[52,53,54] is developing approaches to address these deep uncertainties.

Description of Confidence and Likelihood

Given the robust evidence underpinning this foundational section of the chapter, along with high agreement about that evidence (see especially the foundational assessment by Reed et al. 2022b[3]) Key Message 18.1 is assessed with *high confidence* overall. The first confidence-assigned statement in the Key Message describes the increasing vulnerability of interconnected human–natural systems to risks from climate change. Given the high degree of agreement among voluminous sources of evidence,[1,3,5,12,14,15,16,20,25,26,28,29,30,35,242,248,250], we assign *high confidence* to this statement. The second statement describes how these vulnerabilities depend on human responses and other compounding stressors. Given the high degree of agreement among many sources of evidence (see above), we assign *high confidence* to this statement. The final statement describes the diverse and sometimes competing objectives that decision-makers will need to navigate in managing climate risks. Given the high degree of agreement among ample sources of evidence (see above), we assign *high confidence* to this statement.

Key Message 18.2

Complex Climate Impacts and Responses Further Burden Frontline Communities

Description of Evidence Base

Evidence of the intersectional impacts of natural hazards, decarbonization efforts, and climate adaptation is well documented. Quantitative assessments of program outcomes and post-disaster outcomes, with a large number of data points, consistently show that more rural or smaller municipalities are less able to attract resources for adaptation (e.g., Mach et al. 2019[83]). Numerous case studies and spatial and quantitative assessments provide evidence of the displacement tendencies of climate-exacerbated disasters and climate mitigation and resilience initiatives.[73,85,109,251,252,253] In-depth qualitative research and longitudinal studies of overburdened communities have studied how cyclical disasters erode community response capacity[254,255,256] and trigger cascading infrastructure and housing effects in cities receiving groups migrating from or displaced by climate-related events and trends.[103] Research on the climate transition from fossil fuel economies shows that these efforts intersect with social, cultural, and political challenges to create intersectional vulnerabilities and complexities.[257,258]

Major Uncertainties and Research Gaps

Just as important as what we know about distributive impacts in complex systems is what we do not know or measure. Most research assessing complex systems is highly technocratic, focusing on specific events, discrete risks, and the impacts of cascading infrastructure systems, demographic change, and natural resource systems. However, complexity studies do not tend to encompass the large body of social and

humanities research—increasingly focusing on climate change—related to cultural, psychological, and effective responses to shocks; racial, gender-based, and equity-oriented studies of vulnerabilities, risks, and societal responses; or the roles of political ideology and violent conflict (e.g., Palmer and Smith 2014;[89] Beckage et al. 2020;[87] Moore et al. 2022;[88] Reed et al. 2022,[242] 2022;[3] Rising et al. 2022[90]). These issues can help explain political decision-making, protests, and post-disaster conflicts and are important for understanding interactions across social and physical systems in the near and long term. There is a resulting lack of tools and communities of practice to integrate disciplinary divides in support of complex-systems research.

Limited knowledge about climate-exacerbated migration and how receiving cities are responding results in uncertainties about how climate migration differs from other forms of migration, what migration means for overall vulnerability trends, and how it will impact other interlinked physical and natural systems. Information on urban–rural linkages is limited, especially in forms that can support complex-systems modeling. Trade-offs between mitigation efforts and adaptation strategies with competing impacts on individuals' well-being are also understudied.

Description of Confidence and Likelihood

There is *high confidence* in each statement of Key Message 18.2. First, there is high agreement in the literature that climate change disproportionately impacts already-overburdened groups (statement 1), as recently assessed in the comprehensive Sixth Assessment Report of the Intergovernmental Panel on Climate Change, Working Group II.[69] Second, multiple studies with high agreement across them have documented the lack of social and political dynamics in complex-systems models and limitations resulting from sectoral, regional and jurisdictional, and disciplinary silos of vulnerability and risk assessments (statement 2).[3,86,87,88,89,90,242] Some complex-systems analyses have made first steps in incorporating social and political dynamics (e.g., Moore et al. 2022[88]), but these are emerging efforts, and statement 2 is therefore made with *high confidence*. Third, data about how complex systems affect frontline communities is lacking for hard-to-reach populations, and this can lead to disproportionate climate impacts (statement 3).[97,99] This statement is made with *high confidence* given the large evidence basis on inequalities in data availability and quality across communities and the focus of the literature on data-rich places (e.g., Friel et al. 2011;[98] Pörtner et al. 2022;[69] Reed et al. 2022[3]).

Key Message 18.3

Collaborations Among Diverse Knowledge Holders Improve Responses to Complex Climate Challenges

Description of Evidence Base

Key Message 18.3 and corresponding text draw from a review of various types of literature on knowledge for complex systems, several author team meetings and deliberations over written documents, and takeaways from the public engagement workshop. The write-up was also coordinated with authors of other Key Messages, especially Key Messages 18.2 and 18.4. Literature reviewed for this Key Message spanned several topical areas. The authors reviewed literature describing integrated frameworks and modeling for complex systems,[3,123,126,127,131,136] as well as characteristics of actionable or usable knowledge.[115,116,120,153,154] Authors also focused on literature showcasing the role of qualitative knowledge such as narratives in managing complex systems.[128,129,130] In terms of knowledge production processes, the team reviewed the latest papers on co-production of knowledge and collaborative research approaches, as well as on interdisciplinary and transdisciplinary research.[115,124,147,259] The authors also reviewed literature and case studies on Indigenous and Traditional Knowledges and their role in complex systems, as well as the role of citizen science.[141,142,143,144]

Studies on participatory modeling,[21,140,156,157] as well as collaborative decision-support tools for complex systems such as decision-making under deep uncertainty and scenario planning, were also reviewed. Finally, research on climate services and boundary agencies was also reviewed.

Box 18.3 centers on complex coastal governance, drawing from evaluations of climate responses in Metropolitan regions including the San Francisco Bay area, Los Angeles County, Southeast Florida, and metropolitan New York; a specific case example of the Little River Adaptation Action Area is discussed here. Multiple recent studies have examined the science–policy–practice processes and partnerships, along with the evolving governance systems, inherent to complex coastal climate responses (e.g., Treuer et al. 2017;[260] Kim 2019;[261] Solecki et al. 2021;[262] Tedesco et al. 2021;[179] Troxler et al. 2021;[178] Lubell and Robbins 2022[263]). Direct references are provided to relevant regional strategies and decision support forums (e.g., Miami-Dade County 2021;[176] Miami-Dade County 2021;[175] SFWMD 2021[177]).

Major Uncertainties and Research Gaps

Despite the promise and potential of collaborative knowledge production processes and collaborative decision tools, long-term monitoring and evaluation of these processes and tools are largely lacking; hence, the long-term impact and effectiveness of such collaboratively generated knowledge in responding to complex climate risks in complex systems are not well understood.[147,151,172,264] In addition, the impact of collaboratively generated actionable knowledge on long-term management of complex climate-impacted systems, particularly as it relates to procedural or distributive justice in outcomes, is not well understood.[265]

Description of Confidence and Likelihood

There is high agreement in the literature, from both theoretical[120,124,127] and empirical studies,[117,123,131,263] that effective complex systems responses benefit from integrated frameworks that bring together diverse and context-specific knowledge. Therefore, there is *high confidence* in the first statement in this Key Message. A growing number of studies provide evidence that participatory and collaborative approaches that bring together diverse actors have improved the actionability of knowledge for managing complex systems,[150,151,152] but more evidence is needed on the extent to which this actionable knowledge has actually been used in complex-systems decision-making.[266,267,268] Hence, there is *medium confidence* in the second statement. Although the theoretical literature suggests that collaborative approaches help to navigate competing perspectives of different actors and knowledge uncertainties,[43,117,119] there are very few studies that have evaluated the extent to which these approaches have successfully led to improved climate responses in the long term.[171,267,269,270] Hence, there is *low confidence* in the third statement.

Key Message 18.4

New Governance Approaches Are Emerging, but Gaps in Practice and Evidence Persist

Description of Evidence Base

The subgroup of authors for Key Message 18.4 pulled from a multidisciplinary set of research products at the intersection of governance, regional planning, systems theory, and jurisdictional authority in relation to both climate mitigation and adaptation planning, actions, outputs, and outcomes.[202] The subgroup identified key peer-reviewed research products based on the themes categorized by subgroup members' expertise, as well as the themes that surfaced in the public engagement workshop; essentially, the identification of sources was expansive, but the themes from which the sources were identified and classified were necessarily limited. Further, the subgroup sought to identify documentation of alternative governance successes and

failures in relation to climate mitigation and adaptation in order to expand the pool of sources to other disciplines that may not explicitly use governance terms.[191] For each of the themes identified, there is a vast literature from which to pull findings. Identifying these was a straightforward process, and there was minimal disagreement on either the themes or the sources.

In slight contrast, there was significant discussion regarding the level of confidence around the synthesis of sources' findings, given their range of empirical inquiry and methodological rigor. The vast majority of evidentiary sources rely on either singular governance case studies (or, less often, a few cases) or theoretical exploration in either qualitative or quantitative ways.[195,199] Fewer studies include sample sizes of governance cases that are powerful enough—or that employ comparison groups of any design—to produce conclusive and generalizable findings.[203,221] Consequently, assessments of uncertainties and confidence are based largely on the variable rigor of these sources.

Major Uncertainties and Research Gaps

Governance, by definition, varies by geographic, social, and political landscapes, among many contextual factors. The first factor—geography—poses a particular challenge for the development of conclusive evidence of governance actions and effects.[188] Essentially, each place has a unique governance framework.[117] Although rigorous qualitative and quantitative studies have been conducted regarding governance interventions and their outcomes in specific places, the sample sizes of individual monographs and consistent application of terms across them have consequently produced only preliminary evidence to date. As with urban studies and political geography, there are few multisite studies of complex-systems governance at any level of quasi-experimental rigor, or even basic outcome evaluations, that allow for replicable responses to the fundamental question posed in the public engagement workshop: What is "good" climate governance?

Description of Confidence and Likelihood

This fundamental methodological challenge, then, prohibits an assessment of *high confidence* for all complex-systems governance themes—with the sole exception of their current inability to produce consistently positive outcomes. Further study with larger sample sizes and consistent terms of governance frameworks—including their inputs, activities, outputs, and outcomes—is necessary to assess higher levels of confidence. Statements in the Key Message regarding evaluation/learning, effectiveness, and replicability are therefore made with *low* and *medium confidence*. The quantity of evidence around climate governance implementation and outcomes is too small to conclude that their findings are externally valid and replicable.[203] Policy and governance literature for other subject domains beyond climate mitigation and adaptation for which there has been more extensive study, however, suggests that pilot governance efforts' success may not be insignificant, implying a higher confidence that the implementation of current climate pilots may also yield positive outcomes.[200,224]

Fifth National Climate Assessment: Chapter 19

Economics

Chapter 19. Economics

Authors and Contributors

Federal Coordinating Lead Author

Jeremy Martinich, US Environmental Protection Agency

Chapter Lead Authors

Solomon Hsiang, University of California, Berkeley (through April 2023)

Simon Greenhill, University of California, Berkeley (from April 2023)

Agency Chapter Lead Authors

Monica Grasso, National Oceanic and Atmospheric Administration

Rudy M. Schuster, US Geological Survey

Chapter Authors

Lint Barrage, ETH Zurich

Delavane B. Diaz, Electric Power Research Institute

Harrison Hong, Columbia University

Carolyn Kousky, Environmental Defense Fund

Toan Phan, Federal Reserve Bank of Richmond

Marcus C. Sarofim, US Environmental Protection Agency

Wolfram Schlenker, Columbia University

Benjamin Simon, George Washington University

Stacy E. Sneeringer, US Department of Treasury

Technical Contributors

Daniel Allen, University of California, Berkeley
Clare Balboni, Massachusetts Institute of Technology
Ian W. Bolliger, BlackRock
Judson Boomhower, University of California, San Diego
Hannah Druckenmiller, California Institute of Technology
Teevrat Garg, University of California, San Diego
Miyuki Hino, University of North Carolina at Chapel Hill
Taylor Kee, University of California, Berkeley
Ishan Nath, Federal Reserve Bank of San Francisco
Kimberly L. Oremus, University of Delaware, School of Marine Science and Policy
R. Jisung Park, University of Pennsylvania, School of Social Policy and Practice
Jonathan Proctor, Harvard University
Will Rafey, University of California, Los Angeles

Review Editor

Emily Wimberger, Hua Nani Partners

Introduction

The climate is a national asset that enables and contributes value to diverse economic activities across the United States, from agriculture, finance, and tourism to healthcare, education, and real estate. Changes in the climate are expected to impose substantial new costs to the US economy and adversely affect the economic opportunities of most Americans. Climate change, and the policies adopted in response to it, are also expected to alter both the domestic US economy and the global economy in which the US competes. These economic consequences are projected to be highly uneven across US regions, industries, and communities.

Climate change has *direct* and *indirect* effects on economic outcomes. Direct impacts affect individuals and other basic components of the economy (e.g., buildings, crops). These direct impacts may in turn cause secondary indirect impacts resulting from markets, governments, and other institutions adjusting to direct changes. For example, changes in rainfall patterns and sea level rise put existing homes at risk of flooding, a direct effect. Elevated flood risk in turn causes indirect effects, including lowering home prices, increasing risks to mortgage-providing businesses, and altering the cost of flood insurance provided by the Federal Government.

This chapter assesses the effects of climate change on US markets, budgets, and the economic opportunities of households, businesses, and institutions. This chapter does not assess the economics of climate change mitigation and technological solutions, which are covered elsewhere (e.g., KMs 31.1, 31.2, 17.3).[1,2]

Key Message 19.1

Climate Change Affects the Economy Directly

Climate change directly impacts the economy through increases in temperature, rising sea levels, and more frequent and intense weather-related extreme events (e.g., wildfires, floods, hurricanes, droughts), which are estimated to generate substantial and increasing economic costs in many sectors (*likely*, *high confidence*). These impacts are projected to be distributed unequally, affecting certain regions, industries, and socioeconomic groups more than others (*very likely*, *high confidence*). Adaptation can attenuate some impacts by reducing vulnerability to climate change, but adaptation strategies vary in their effectiveness and costs (*medium confidence*).

Observed Direct Impacts

Direct economic impacts of climate change have been observed in many economic sectors (e.g., Table 19.1a). For example, more frequent extreme events and higher temperatures lead to direct economic losses via infrastructure damage,[3] worker injuries,[4] and crop loss.[5]

Climate change also directly affects valuable resources that are not traded in markets, such as human health and ecosystems. These *nonmarket impacts* are sometimes difficult to quantify but are nonetheless economically important and represent a substantial fraction of the economic burden of climate change on Americans (Table 19.1c). For example, rising temperatures, extreme weather, wildfires, vector-borne diseases, food insecurity, and knowledge of the threat of climate change itself have all been linked to declines in Americans' physical and mental health.[6,7,8,9,10] Additionally, changes in ecosystems caused by climate change have impacted food production, water resources, forestry, human health, real estate values, recreation, and tourism (KM 6.1, 7.3).[11,12,13]

Projected Direct Impacts

While some economic impacts of climate change are already being felt, the impacts of future changes are projected to be more significant and apparent across more sectors of the economy (e.g., Figure 19.1 and Table 19.1b). With every additional degree of warming, the United States is expected to see increasingly adverse consequences. For example, warming global temperatures by 2°F is projected to cause more than twice the economic harm induced by 1°F of warming.[14,15]

As climate change advances, economic risks are projected to grow over time. For example, weather-related disasters currently generate at least $150 billion per year (in 2022 dollars) in direct damages to the US,[16] a cost that is projected to increase due to climate change in the near term.[17,18,19] Over the next few decades, climate change is projected to cause ecosystem disruptions,[20] water stress,[21] and agricultural losses.[22,23,24,25,26,27,28] Over the coming century, the country faces relocation costs and damage to property and infrastructure due to coastal flooding,[29] major adverse impacts on ecosystem services,[30] substantial and unequal health costs,[7] large negative impacts on economic production,[31] and a restructured investment landscape.[32]

While many sectors are impacted by changing weather conditions, agriculture is also directly impacted by higher carbon dioxide (CO_2) levels, because plants use CO_2 during photosynthesis. The effect of a CO_2-enriched environment is not well understood and depends on crop types and the availability of water and soil nutrients.[33] In some cases, CO_2 enrichment increases biomass but causes the nutritional value of agricultural output to decline.[34] Overall, the risks climate change poses to agriculture are expected to outweigh any potential benefits due to CO_2 fertilization or other factors such as longer growing seasons and expanded crop ranges (KMs 11.1, 21.1, 22.4, 23.3, 24.1, 26.2).

Projected economic impacts are not certain, as they depend on factors that cannot be known precisely. The largest source of uncertainty in projected impacts is the unknown trajectory of future greenhouse gas emissions,[35] which depend on mitigation policy, economic development, population growth, and other factors (KM 2.3). The uncertainty caused by climate change is itself an economic burden, since individuals are generally risk averse (Box 19.1).[36,37]

Economic impacts of climate change will vary by location due to different hazards, regional climate change patterns, and historical climate (Figure 19.1; KM 3.4). For example, locations that are hot today are generally projected to suffer greater damage because warming from 100°F to 105°F has a larger effect on human health, energy use, labor supply, and crop yields than warming from 60°F to 65°F.[7,26,38,39] Population density also influences the local economic impacts of climate change, since dense populations exacerbate urban heat islands and groundwater drawdown but improve the cost effectiveness of some public adaptation projects, such as seawalls.[40,41]

Cold regions may benefit from low levels of warming while temperate and hot regions are generally harmed.[15] Within most sectors that have been studied, more Americans are harmed than are helped by climate change (Figure 19.1b).[3,7,42,43,44,45,46,47] Estimates of nationwide impacts indicate a net loss in the economic well-being of American society (Figure 19.1c; e.g., Hsiang et al. 2017;[15] Rode et al. 2021,[46] 2022;[45] Hultgren et al. 2022;[43] Carleton et al. 2022;[7] Martinich and Crimmins 2019[44]).

Table 19.1. Example US Economic Impacts of Climate Extremes and Climate Change

Shown are observed and projected impacts of a sample of climate extremes and climate changes on US economic outcomes, as they are estimated in the context of particular studies. Note that only a subset of climate drivers may have been assessed in each study. Section (**a**) shows impacts on current economic outcomes. Section (**b**) shows projected future impacts. Section (**c**) highlights examples of important but unquantified impacts. All impacts are for the US and in 2022 dollars unless otherwise noted. GDP stands for gross domestic product, a standard measure of total domestic economic production. These estimates are illustrative and not comprehensive. See metadata for table credits.

Key: * indicates an intermediate scenario (e.g., RCP4.5); ** indicates a high scenario (e.g., RCP6.0); *** indicates a very high scenario (e.g., RCP8.5); † indicates 3% discount rate.

a) Sample Current Impact Estimates of Climate Hazards on US Economic Outcomes

Sector	Impact Type	Climate Hazard	Economic Estimate
Government, Agriculture	Crop insurance payouts	Temperature increases	+19% of federally subsidized payouts[48]
Agriculture	Rural outmigration	Warming-linked crop failure	+0.17% for 1% crop yield reduction[49]
Business	Commercial mortgage delinquency	Hurricane	+28% per 10% damage increase[50]
Business	GDP growthW	Hurricane	−0.45 percentage point annual growth rate per hurricane[51]
Government	Municipal borrowing costs	Sea level rise	+23.4 basis points annualized bond issuance cost per 1% additional GDP loss due to sea level rise[52]
Government	Municipal budgets	Wildfire	+25 percentage point increase in likelihood of budget deficit[53]
Government	Social safety net transfers	Hurricane	+$975–$1,440 per capita[54]
Households	Housing prices	Flooding	−4.6% (in 100-year floodplain)[55]
Households	Student learning	Temperature increases	1% decrease in test scores per 1°F hotter school year (no adaptation)[56]
Infrastructure	Property values	Sea level rise	−14.7% (1-foot rise)[57]
Agriculture, Infrastructure	Damage to structures and crops	Flooding	+$235 billion per year[58]
Labor	Earnings	Wildfire smoke	−$144 billion per year[59]
Labor	Work injuries	Heat (≥85°F day)	+5%–15% per hot day[4]

Sector	Impact Type	Climate Hazard	Economic Estimate
	Wages as adult	Heat (≥90°F day)	−0.1% per hot day in utero[60]
	Emergency department costs	Heat (≥80°F day)	+$10,600 per 100,000 people aged 80+[61]
	Mortality	Heat (≥90°F day)	+0.9 deaths per 100,000 people[62]
	Alaska Native village relocation	Warming-linked erosion	$28–$280 million costs per village (adaptation only)[63]

b) Sample Future Impact Estimates of Projected Climate Hazards on US Economic Outcomes

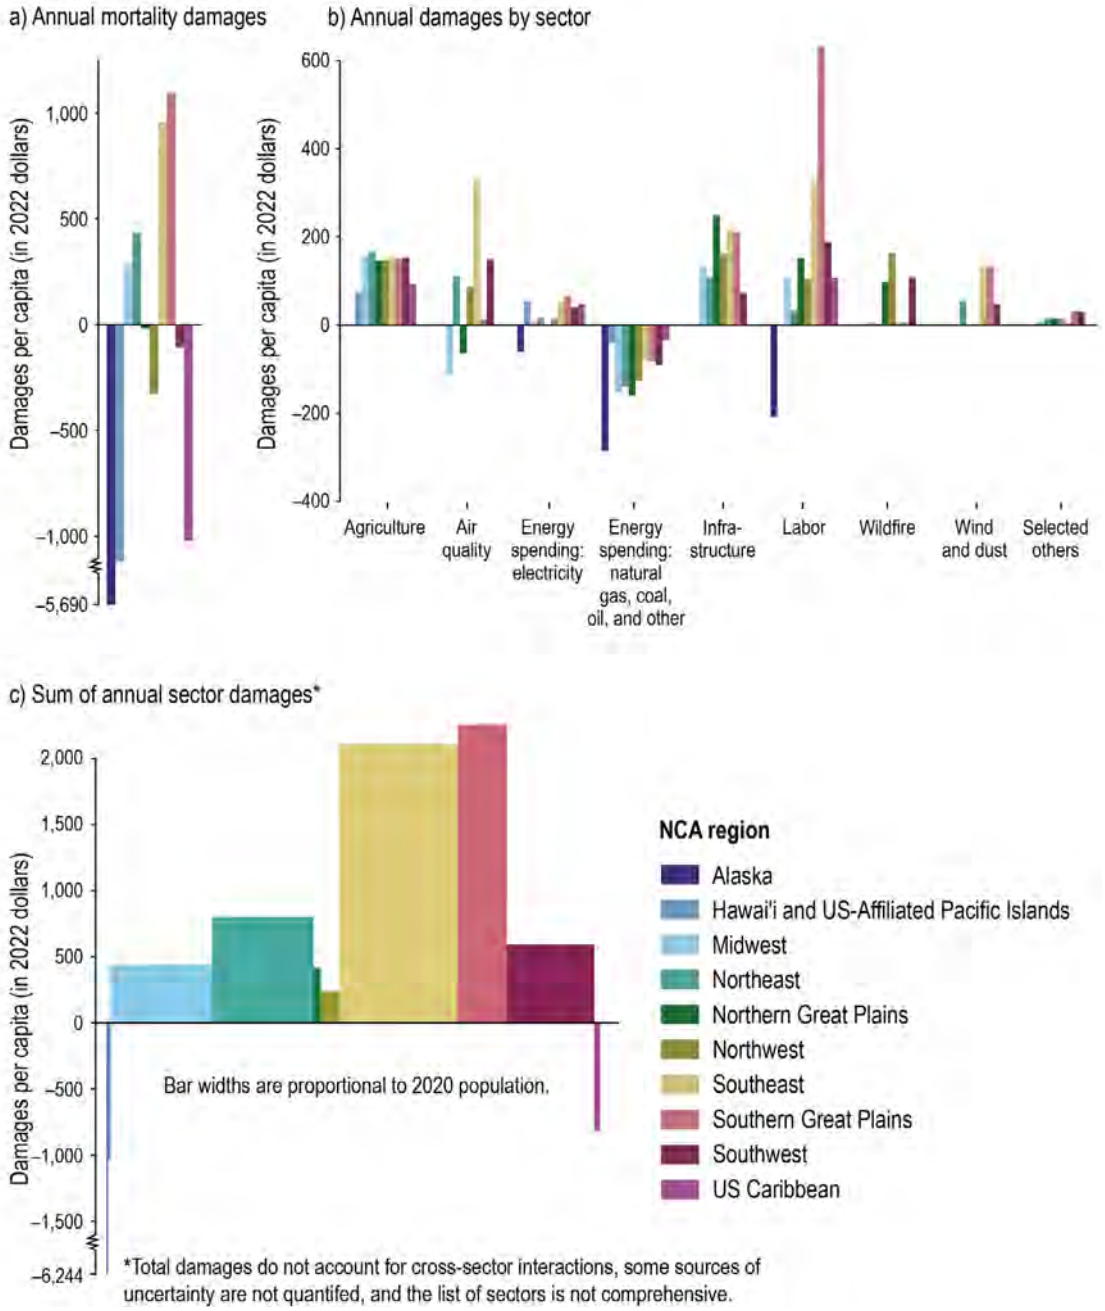
Sector	Impact Type	Climate Hazard	Economic Estimate
	Agricultural yields (maize, soybeans, winter wheat, spring wheat, cotton, and sorghum)	Temperature, moisture changes	12%–29%* decrease (2050–2100)[21] 20%–48%*** decrease (2050–2100)[21]
	Agricultural yields (maize, soybeans, and cotton)	Temperature, precipitation changes	30%–46%* decrease (2070–2099)[26] 63%–82%*** decrease (2070–2099)[26]
	Aggregate multisector impact	Temperature increases	−0.1%–1.7% GDP loss*[15] 1.5%–5.6% GDP loss***[15]
	Airline network disruption	Temperature increases	+16%–50% recovery costs (2035, global)***[64]
	GDP growth	Temperature increases	−0.13 percentage points per year per 1°F warming[31]
	Income	Temperature increases	−19.6% global GDP per capita (3°C [5.4°F] of warming)[31]
	Income	Hurricanes	29% GDP loss**†[65]
	Federal disaster response	Hurricanes	+$5.2 billion* (2050 annual expenditures)[66] +$36 billion*** (2050 annual expenditures)[66]
	National Flood Insurance Program	Flooding	+$3.9 billion annual losses (2050)*[66] +$5.1 billion annual losses (2100)*[66]
	Property tax revenue	Sea level rise	−1.4% (3-foot rise)[67]
	Public services	Temperature increases	+1.45% costs (2050)***[68]
	Coastal damages	Sea level rise	+$550 billion (optimal adaptation)***[40] +$2.6 trillion (no adaptation)***[40]

Sector	Impact Type	Climate Hazard	Economic Estimate
	Electricity outages	Temperature, precipitation changes	+$2.3–$6.8 trillion consumer costs***[69]
	Flooding costs	Flooding	+61% annual losses (2050)*[70]
	Railroad disruption	Temperature increases	+$30–$55 billion* costs from network delays[71] +$43–$73 billion*** costs from network delays[71]
	Road degradation	Temperature, precipitation changes	+$116 billion*** costs†[29]
	Urban drainage degradation	Temperature, precipitation changes	+$29 billion*** costs†[29]
	Alaska Native village relocation and protection costs	Flooding, erosion, permafrost subsidence	+$3.9 billion over 50 years (adaptation only)[72]
	Migration from Mexico to US	Temperature, precipitation changes	+0.7 million* migrants[73,252,253] +3.2 million*** migrants[73,252,253]
	Mortality (all causes)	Wildfire	+9–20 deaths per 100,000 people ≥65 years old (for 50% increase in smoke)[74]
	Suicides	Temperature increases	+5,600–26,000 deaths by 2050***[6]
	Recreation (boating, cycling, hiking, running, water sports)	Temperature, precipitation, snowfall changes	$11.6 billion (annual welfare gains 2050–2100)***[75]
	Recreation (fishing, hunting, skiing, ice skating, snowboarding)	Temperature, precipitation, snowfall changes	$4.6 billion (annual welfare losses 2050–2100)***[75]

c) Sample Impacts That Are Difficult to Quantify in Economic Terms

Sector	Impact type	Climate hazard	Economic estimate
	Happiness	?	?
	Preservation of national landmarks	?	?
	Loss of cultural heritage and resources	?	?
	Subsistence activities	?	?

Example Projected US Economic Damages for 3°F of Global Warming



Projected economic impacts of climate change vary by sector and region, with aggregate impacts resulting in net damages nationally.

Figure 19.1. Shown are estimates of annual economic damages in each National Climate Assessment region for several sectors in a scenario where global surface temperature increases 3°F (1.67°C). Positive damages indicate harm and negative damages indicate benefits. Panels (**a**) and (**b**) show per capita damages by region broken down by sector. Panel (**c**) shows summed per capita damages across sectors by region, with bar width corresponding to 2020 population. Most regions experience positive damages in most sectors. In aggregate, nearly all regions and the vast majority of the American population are projected to experience economic harm from climate change. Note that these damages do not account for cross-sector interactions, some sources of uncertainty are not quantified, and the list of sectors is not comprehensive. See Table 19.1 for further examples of sectors impacted by climate change. Citations for each study underpinning these results are available in the figure metadata. Figure credit: See figure metadata for contributors.

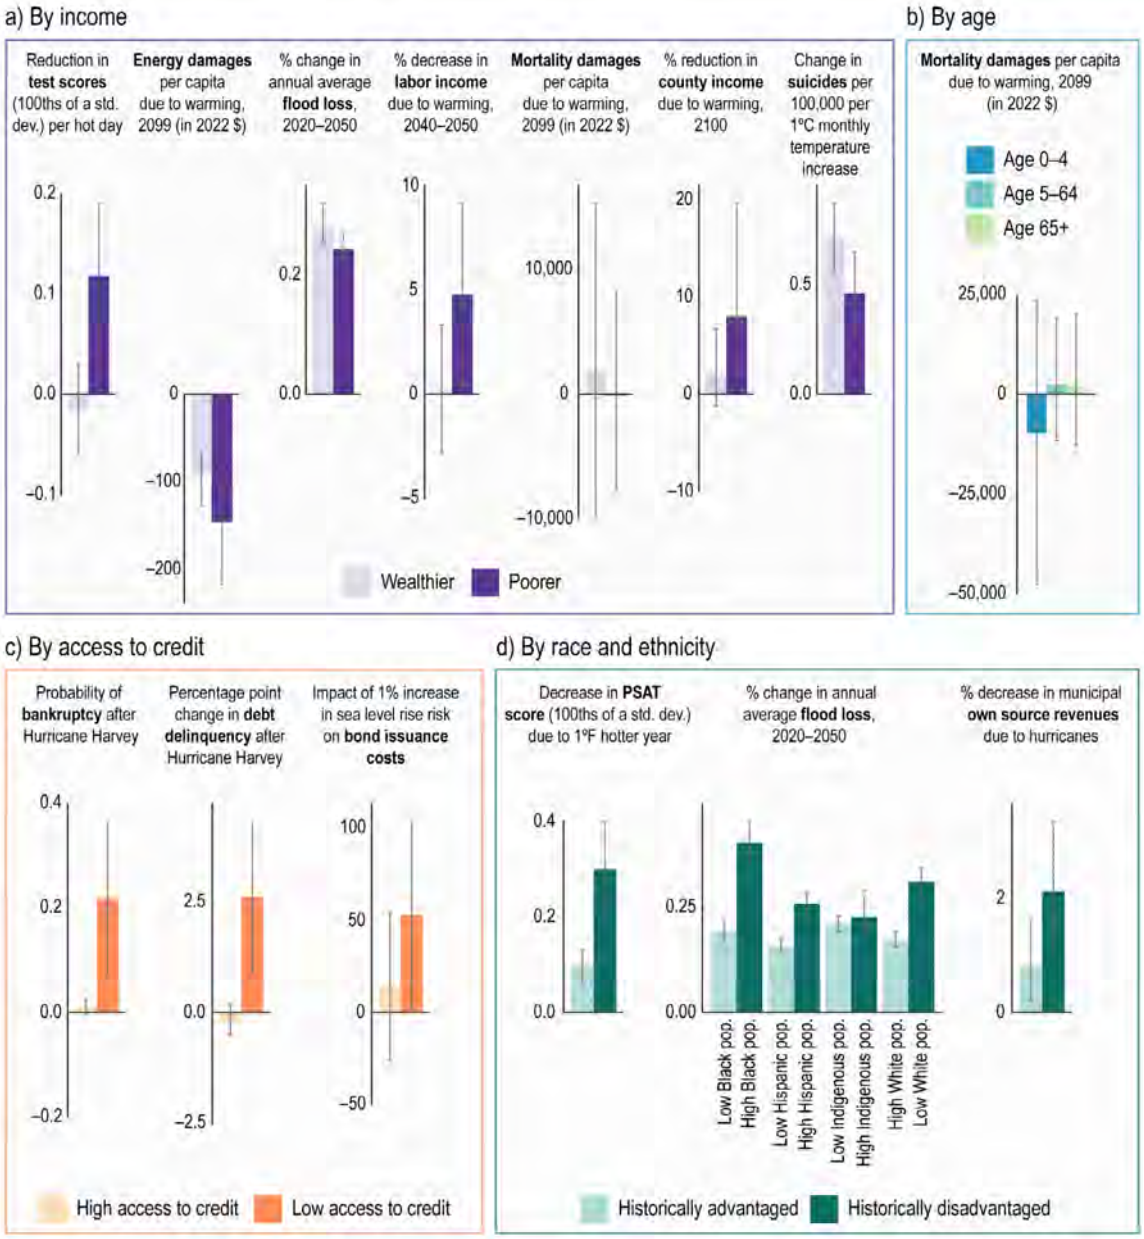
Adaptation

Adaptation to climate change can reduce some economic impacts.[38,40] For example, adaptation is expected to reduce storm-related climate damages by approximately one-third.[76] In some sectors, however, there is limited scope for adaptation (Ch. 31).[77,78] Natural and human systems may not be able to adapt quickly, so gradual warming is expected to be less harmful than rapid warming.[40] Adaptation can occur when populations have access to technologies or opportunities that lower their vulnerability to harmful conditions at sufficiently low cost.[41,79] Around 1% of the US capital stock is estimated to be adaptation capital.[76] Some adaptation strategies require new investments, expenditures, or consumption changes that offset or outweigh their benefits.[7,80,81] These adaptation costs may be large enough to prevent existing technologies from being utilized, particularly among low-income communities.[41,46] Adaptation may also face political difficulties, require behavior changes that populations are reticent to adopt,[82] or depend on technologies that do not yet exist or are in their infancy.[83] These factors make the projected timing and effectiveness of adaptations uncertain.[77]

Economic Vulnerability and Inequality

Economic damages from climate change are distributed unevenly across American society, often amplifying existing inequalities (Figure 19.2). Certain communities and individuals are more sensitive to climate impacts, are more exposed to climate hazards, or lack the resources to adapt to climate changes and recover from damages caused by natural hazards.[18,46,76,84,85,86,87,88,89,90,91,92] For example, people with preexisting health conditions and older adults may be relatively more sensitive to heat or air quality impacts such as wildfire smoke (KMs 14.3, 15.2).[4,93] Families living below the poverty line often live where climatic changes are expected to be the most economically damaging, like the already-hot Southeast (KMs 22.3, 22.4).[15] Climate-driven relocations of Alaska Native communities have already occurred where warming is happening fastest (KMs 16.1, 29.3, 29.5).[94,95] Climatic stressors have also been shown to increase racial segregation,[96] gentrification,[97] income inequality,[98] and low-income communities' reliance on social safety net programs and credit systems.[54,85,99] Climate change also introduces fiscal risks (Figure 19.3; KM 19.2) that may threaten programs vulnerable communities rely on.[100] Broad research gaps remain about unequal climate change impacts across demographics, health status, and socioeconomic background.

Climate Damages by Income, Age, Access to Credit, and Race and Ethnicity



The effects of weather and climate change are often experienced differently by populations according to income, age, access to credit, and race and ethnicity.

Figure 19.2. Each bar plot summarizes findings from a single study with impact estimates for different groups. Whiskers represent 95% confidence intervals, with the exception of the whiskers on the multisector aggregate panel, which are 90% confidence intervals. (**a**) The first set of estimates show unequal impacts by wealth. (**b**) The second set of estimates show unequal impacts across age groups. (**c**) The third set of estimates show unequal impacts by credit access. (**d**) The fourth set of estimates show unequal impacts by historically advantaged and disadvantaged populations. The citations for each study are available in the metadata. Many of these estimates are uncertain, and differences between groups are often not statistically significant. Further examples of unequal climate impacts within National Climate Assessment regions are available in Figure 22.4 and Key Message 20.1. Figure credit: See figure metadata for contributors.

Key Message 19.2

Markets and Budgets Respond to Climate Change

Markets are responding to current and anticipated climate changes, and stronger market responses are expected as climate change progresses (*medium confidence*). Climate risks are projected to change asset values as markets and prices adjust to reflect economic conditions that result from climate change (*very likely*, *high confidence*). New costs and challenges will emerge in insurance systems and public budgets that were not originally designed to respond to climate change (*high confidence*). Trade and economic growth are projected to be impacted by climate change directly and through policy responses to climate change (*likely*, *medium confidence*).

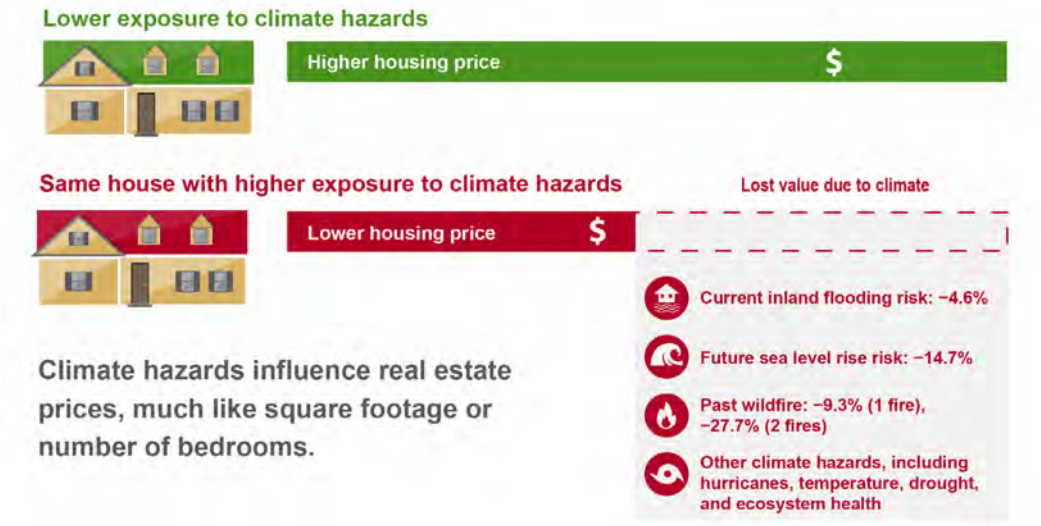
Markets

Markets aggregate information from many individuals and firms, generating system-level outcomes (e.g., market prices). Prices in well-functioning markets will reflect assets' exposure to future climate risks and expected adaptation costs. For example, anticipation of future flood risk has begun to reduce the prices of vulnerable properties (Figure 19.3).[57,101] But there are barriers that sometimes prevent market prices from adjusting to reflect climate risks,[102] such as inaccurate information or incomplete understanding of relevant climate risks.[103,104,105,106] Increasing awareness of climate change is expected to tighten the link between asset prices and climate risks in financial markets and may lead to abrupt price adjustments.[52,57,107,108,109]

Changes in prices due to climate change can have different impacts on producers and consumers. For example, higher temperatures around the globe are expected to lead to a reduction in global production of corn, wheat, rice, and soybeans.[43] This reduction in supply is expected to increase crop prices.[110] In some cases, these higher prices could financially offset the reduction in yields for farmers, but US consumers would face the burden of the higher food prices.[111]

Insurance markets are important for financial resilience to changing climate extremes, but insurance coverage is costly, and prices may exceed what households and businesses are willing or able to pay.[112] As the risk of climate extremes grows, private insurers are expected to abandon high-hazard areas, as is occurring in some wildfire- and hurricane-prone locations.[113] Uninsured consumers face greater financial distress post-disaster,[114] and public-sector insurance programs, such as crop insurance and the National Flood Insurance Program, see increasing demand when private insurance markets contract. To account for the growing risks, fiscal costs of public insurance programs will rise.[66,115]

Stock and bond market prices generally reflect anticipated climate risks,[116] but pricing can be incomplete or distorted.[102,117] Anticipated policies to curb emissions can impact stock prices of emissions-intensive companies,[108,118] and long-term bonds issued by municipalities exposed to future climate risks tend to have lower prices.[52,119] In the absence of strong global mitigation policies, some forward-looking financial institutions are preemptively responding to potential impacts by restructuring portfolios.[120,121]



Exposure to climate hazards has a negative effect on real estate values.

Figure 19.3. Exposure to past climate events and to present and future climate risks affects the values of otherwise identical properties. The market price for real estate is reduced when the property is exposed to adverse climate extremes or risks. Percentages shown are example estimates from studies. Homes located in the present-day 100-year floodplain cost 4.6% less than comparable homes outside the floodplain;[55] homes projected to be inundated by 1 foot of sea level rise cost 14.7% less;[57] and homes located near one recent wildfire cost 9.3% less, while those located near two recent wildfires cost 27.7% less.[122] Note that these are examples from specific studies, some of which are not nationally representative. Other climate hazards including hurricanes,[123] droughts,[124] temperature,[125] and ecosystem health,[126] among others, also affect real estate prices. Figure credit: See figure metadata for contributors.

Public Budgets, Healthcare, and Infrastructure

Climate change will affect public budgets at all levels of government through changes in revenues, spending, and borrowing costs (Figure 19.4).[127,128,129] For example, sea level rise, wildfires, and hurricanes can decrease incomes[65,130] and housing values (Figure 19.3),[109,131] and thus tax revenues,[100] while simultaneously increasing public expenditures for healthcare, income support,[54] disaster assistance,[132] and defense spending.[133] This combination of declining revenue and increasing expenditures increases municipal borrowing costs.[52,53,100,119]

Climate change is expected to further increase the costs of public programs, such as crop insurance subsidies,[48,115] wildfire suppression,[66,134,135] endangered species protection,[136] and healthcare provision.[68,137,138] Given these demands, achieving sustainable public budgets in a changing climate is expected to require additional revenues or other expenditure reductions.[68,128]

US healthcare is provided by public systems and private markets, both of which will be impacted by climate change. Extreme weather events, such as hurricanes, damage healthcare facilities and impede medical care delivery[139,140,141] and create competition for healthcare services.[142] The direct health impacts of climate change (e.g., Ch. 15; Limaye et al. 2019[143]) are expected to generate higher medical costs, raising health insurance premiums, out-of-pocket spending, and expenditures on prevention efforts.[7,144,145]

Essential infrastructure, such as water, energy, communication, and transportation systems, will increasingly be compromised by the compounding effects of climate change impacts (Chs. 4, 5, 12, 13; Focus on Compound Events). Degradation or disruption of these assets, many of which are publicly owned, can have substantial repercussions on other sectors and the well-being of households (Table 19.1).

Migration, Trade, and Growth

Future climate changes are expected to affect migration patterns, although how these shifts will occur is uncertain. Historical events that have shaped migrations include extended droughts, which drove rural populations toward urban centers,[124] and hurricanes, which have had persistent impacts on where people live.[146,147,148] Projections of increased flood risks due to sea level rise (KM 2.2) are expected to displace substantial populations.[149,150,151] Climate-driven economic changes abroad, including reductions in crop yields, are expected to continue increasing the rate of immigration to the United States.[73,152]

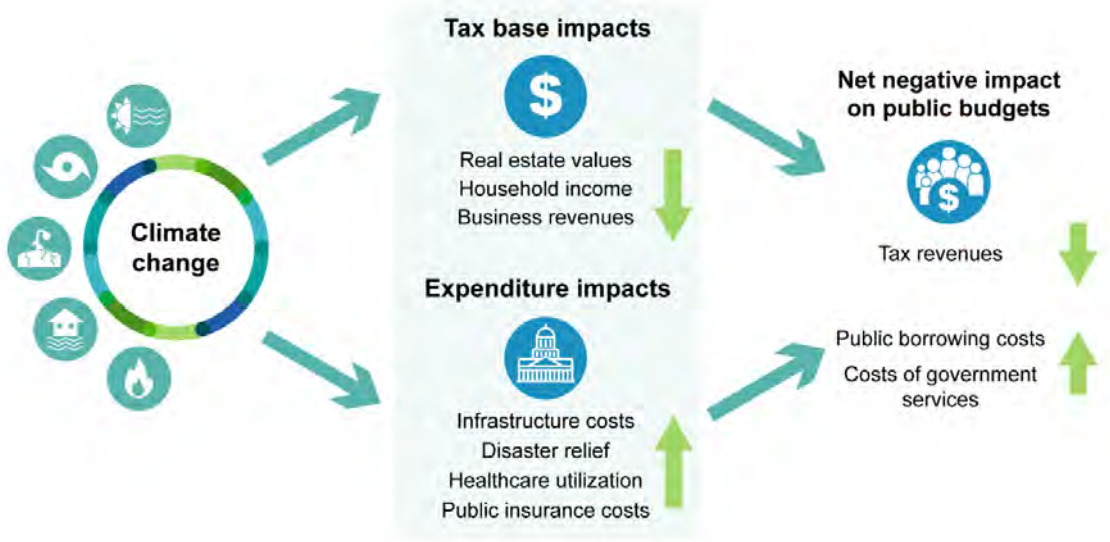
Global supply chains can transfer, amplify, or reduce the direct impacts of climate change (Focus on Risks to Supply Chains). Climatic events in other countries impact trade with the United States,[153] which in turn affects domestic markets (Ch. 17).[154] Climate impacts that affect multiple countries simultaneously amplify costs due to interacting disruptions and linked trade.[155] However, geographic diversification of supply chains would allow for businesses to flexibly adjust supplies to partially reduce their exposure to climate-associated risks.[156]

High annual temperatures and tropical cyclones are associated with lower growth in GDP,[31,65,157,158] with responses from multiple industries contributing to this overall effect. For each 1°F increase in global average surface temperature, annual US GDP growth is projected to slow roughly 0.13 percentage points,[31,157,158] with larger effects for larger temperature changes. These changes in growth rates can in turn affect stock market prices and interest rates.[159,160]

Innovation

Economic impacts of climate change will motivate some investments in innovations aimed at reducing or limiting climate damages. For example, development of low-cost air-conditioning[38] and arid-tolerant crop varieties reduced the impact of historical climate conditions.[161] Future innovations may reduce costs or result in new adaptation technologies. However, some adaptation challenges have proven difficult to overcome,[162] and novel adaptive technologies are sometimes costly, often limiting their accessibility to high-income communities.[46] Nonetheless, strategic investments in key adaptation technologies have the potential to generate large social and private returns.

Fiscal Risks of Climate Change



Climate change puts pressure on public budgets.

Figure 19.4. Climate change increases demand for government services while also reducing governments' ability to fund those services, creating new risks for the fiscal sustainability of government budgets at local, state, and federal levels. Tax revenues may fall due to decreased real estate values, household income, and business revenues.[53,100,163] Meanwhile, expenditures on infrastructure,[164] disaster relief,[132] healthcare,[54,68] and public insurance[135] are expected to increase. Together, this fiscal risk increases the cost to government for borrowing funds (e.g., the sale of bonds) by reducing the rating of public debt, which in turn further harms the ability of governments to fund services. Figure credit: See figure metadata for contributors.

Box 19.1. Economic Decision-Making Under Uncertainty

Economists use economic and financial models to understand the potential impacts of climate change on our economy and markets. Projected economic outcomes depend on many uncertain factors, including technological developments, economic growth, mitigation policies, individual behavioral responses, and Earth system processes. Recognizing this uncertainty is important for decision-making and should be factored into economic planning and risk analysis.

Economic uncertainty due to climate change is costly. Individuals and investors dislike uncertainty as it can drive up costs of action by requiring planning for multiple possible futures. Society thus benefits from actions that can reduce this uncertainty (e.g., obtaining better information on damages). When uncertainty cannot be reduced, some investments may be valuable specifically because they serve as a hedge against climate risks,[159] and it may be prudent to preserve and develop options and invoke decision strategies that seek robustness against a range of future outcomes. For example, in the face of uncertainty around future climate conditions, the California Public Utilities Commission now asks energy utilities to use downscaled climate projections for a very high scenario (RCP8.5) for climate adaptation planning, investment, and operational purposes (see KM 18.3).[165]

Key Message 19.3

Economic Opportunities for Households, Businesses, and Institutions Will Change

Climate change is projected to impose a variety of new or higher costs on most households and to impact their employment, income, and quality of life (*very likely*, *high confidence*). Climate change will alter the economic landscape that businesses face, generating new risks but also creating new opportunities (*likely*, *medium confidence*). Institutions and governments are expected to see existing programs used more intensively or in new ways as populations cope with climate change, generating new system-wide risks (*medium confidence*). Design, evaluation, and deployment of adaptation technologies and policies will strengthen our national preparedness for climate change (*high confidence*).

American Households

Climate change will have different economic implications for American households depending on their occupation and where they live.[84,157] On average, climate change is projected to reduce future income gains compared to what households would achieve in the absence of climate change.[166]

Climate change is expected to impact employment by changing demand for workers, reducing worker safety,[4] altering the location of available jobs,[49] and changing workplace conditions in heat-exposed jobs.[45,167] Households may also lose wealth through declines in the value of real estate (Figure 19.3).

Climate change will affect household spending,[168] for example, by changing energy use (Ch. 5),[169] increasing medical costs (Ch. 15),[143] elevating food prices (Ch. 11),[111] raising insurance premiums, and requiring more frequent repairs and replacement of assets damaged by extreme events.[16]

Children's economic prospects will be affected by climate change. For example, higher temperatures in utero negatively impact adult economic outcomes,[60] while higher temperatures during childhood reduce learning[56,170] and cognitive performance.[171,172]

Climate change is expected to alter the quality of life for American households[125] by reducing life expectancy,[7] increasing crime and domestic violence,[15,173] damaging sleep quality,[174] harming mental health,[6,175] reducing happiness,[176] and altering recreation in both positive and negative ways (Table 19.1).[75,177,178,179]

Adapting to climate change generates new household costs and can alter living and work arrangements. For example, homes may be relocated or retrofitted to withstand weather extremes,[180,181] and consumption patterns may change to offset harms from the climate.[62] Importantly, lower-income households may face greater risks from climate change and have fewer resources to support the costs of adaptation (KMs 22.3, 22.4).[98]

American Businesses

Climate change is projected to reduce labor productivity and economic output across many sectors—including agriculture, finance, real estate, insurance, and services—and across many regions and states.[15,80,157] Extreme weather events can reduce output for extended periods, altering GDP growth rates.[158] In projections, these effects can compound over time, generating large cumulative losses.[9,31,157,182]

Businesses will face increasing exposure to climate-related risks at local, national, and international levels. For example, more intense heatwaves will reduce local productivity, greater wildfire smoke will lower

demand for outdoor services, and more frequent extreme events around the world will disrupt international trade, supply chains, and foreign demand for American products (KM 17.3).

Climate change will also affect business investment planning. For example, the location of firm capital investments may change in response to more frequent weather disasters,[183] and regional adaptation efforts may be funded via corporate taxes or impact the rate of return on other investments.[184] Investment strategies for climate-resilient technologies and the total cost of insurance for capital investments are both expected to be impacted by climate change. In addition, uncertainty in impacts and the effectiveness of adaptation may delay investments (see Box 19.1).

The management of climate-related business risks can draw on established practices for general risk management. For example, regulators and investors are increasingly requiring businesses to disclose climate risks and management strategies. To support this, risk assessment tools for quantifying physical risks are currently being developed in public and private sectors.[185,186]

Governments and Institutions

Local, regional, national, and international governments and institutions (e.g., universities, professional associations, nongovernmental organizations) play a major role in facilitating individual and coordinated adaptation responses and enabling cost-effective decisions. Federal agencies are required to develop adaptation plans[187] and assess and mitigate climate-related financial risks,[188] while some states, local governments, and Tribal governments are developing plans varying in scope and complexity (KMs 31.1, 31.3, 31.4, 32.5).

Governments at all levels would benefit from preparing for the fiscal impacts of climate change, considering impacts on revenues, expenditure requirements (e.g., healthcare, income support), and borrowing costs.[53,68,128] Reducing the overall societal cost of extreme events may be possible through investments in public infrastructure, healthcare, and community resilience programs[189,190,191] and through public support for private adaptation, including fiscal support,[76] updated building codes (Ch. 12),[192,193,194] and better climate-risk information and disclosures.[195] Such public programs also have the potential to reduce the inequitable impacts of climate change.[98,196] Financial preparedness by households and public entities, such as through insurance take-up,[52,197] improved credit,[52,85] and specialized financial instruments,[198] can shift risk or reduce losses. However, public insurance support or provision can decrease incentives for private adaptation.[76,199]

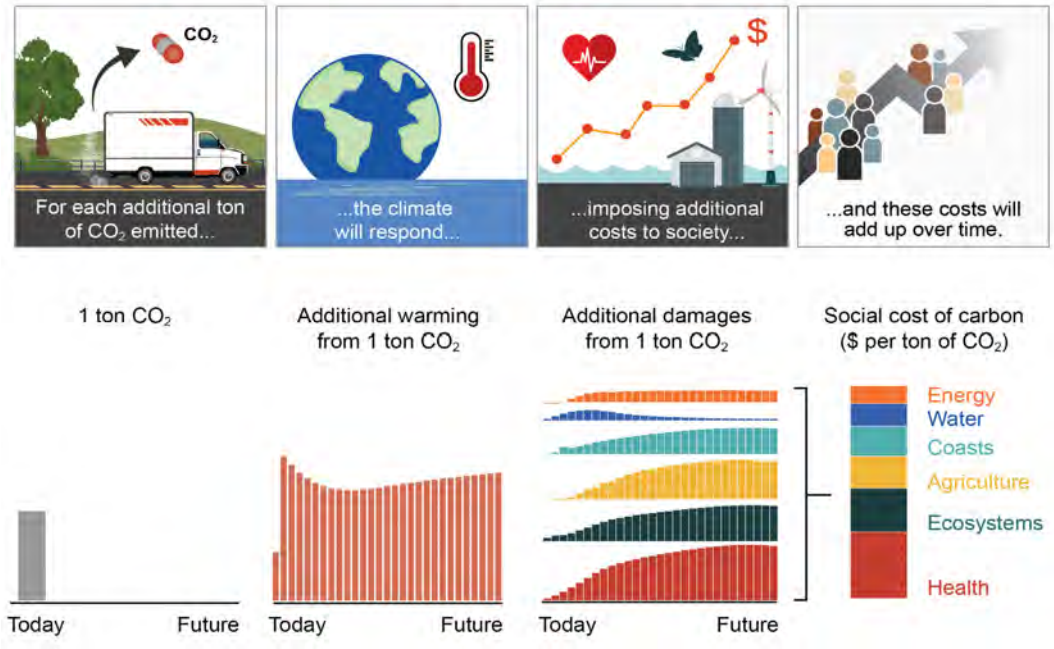
It is sometimes important for governments or institutions to quantify the overall economic impact of climate changes caused by certain current activities, for example, in analyses of whether the benefits of a new climate policy exceed its costs. A succinct summary description of the benefits of emissions reductions widely used in economic analyses is the "social cost of greenhouse gases," defined as the cumulative global economic harm to society caused by additional greenhouse gas emissions (Figure 19.5).[200] Institutions and governments considering the economic consequences of emissions may find estimates of this measure helpful, although they should familiarize themselves with the analytical and ethical judgments used in its construction. In 2010, twelve agencies from the Federal Government developed a process for estimating the social cost of greenhouse gases and periodically updated it based on scientific advances.[201] The current interim estimate used by the Federal Government, adjusted to 2022 dollars, is $57, $1,700, and $20,000 per ton of carbon dioxide, methane, and nitrous oxide, respectively, for 2020 emissions using a 3% discount rate.[201] There is ongoing research to update these values in accordance with recommendations from the National Academies of Sciences, Engineering, and Medicine.[200]

There is growing concern that climate change could pose a systemic risk to financial stability.[202,203,204,205,206,207] Negative economic impacts on even a limited number of entities could, in principle, lead to cascading effects, causing wider failure in the financial system. For example, declines in property values due to climate

change could adversely affect mortgage markets and financial institutions' balance sheets, potentially leading to financial distress, especially if climate risks are imperfectly priced or if they are concentrated in government-sponsored enterprises.[202,206,207,208,209,210] While more research is needed to understand these systemic effects, some underlying risks can be managed. For example, the risk of future asset price corrections, driven by misalignment between current prices and the expected effects of climate change,[57,101,102,103,109,211] can be reduced through communication and disclosure of climate risks to market actors.[109,195]

Climate change has the potential to undermine conditions that support overall societal stability, which may threaten economic stability, and vice versa. Global warming has the potential to impede the ability of institutions and governmental organizations to function smoothly[175,212] and to increase political turnover,[213] and it is directly implicated in increasing rates of violence and unrest.[214,215] Some extreme events have triggered widespread mortgage delinquency,[216] insurer default,[217] breakdown in support for leaders,[218] and the migration of large populations domestically[219,220] and internationally[221,222]—which in turn impacts downstream markets.[146,223] Coping with these destabilizing effects may require investment in systems that buffer and stabilize economic and social conditions, such as social safety nets, insurance, defense spending, and confidence-building mechanisms.[54,133,224]

The Social Cost of Greenhouse Gases



The social cost of greenhouse gases is a monetary estimate of the total economic impact of an additional greenhouse gas emission today.

Figure 19.5. The social cost of greenhouse gases provides an estimate of the economic benefits to society of mitigating emissions, which can then be compared against the costs of doing so. This conceptual illustration shows how the social cost of reducing emissions of a particular greenhouse gas is computed. From left to right, the effect of one ton of carbon dioxide (CO_2) emitted into the atmosphere is illustrated in terms of additional warming or other physical impacts like sea level rise; these changes are translated into costs and benefits expected in representative market sectors such as agriculture, energy services, and water and coastal resources, as well as nonmarket impacts to human health and ecosystems; lastly, impacts that occur around the world and into the future are added up into a single measure using weights that reflect preferences around time, risk, and equity. The values shown in the figure are illustrative and may differ from estimates used for regulatory purposes. Figure credit: See figure metadata for contributors.

Traceable Accounts

Process Description

The chapter lead author was identified in July 2021, and the author team was recruited in July–August of 2021. Authors were selected based on their expertise on broad topics critical to the economic impacts of climate change on the US economy. Technical contributors were recruited by January of 2022 and were identified based on their expertise on specific types of impact. Efforts were made to ensure that both the author team and technical contributors represented a diverse range of backgrounds from across the country, including representation from academia, the private sector, nongovernmental organizations, and economic units of the Federal Government. The Economics chapter hosted an online engagement workshop on January 31, 2022. The authors also considered other outreach with stakeholders and inputs provided in the public call for technical material and incorporated the available scientific literature to write the chapter.

Discussion within the team during multiple virtual meetings and email exchanges, along with consideration of a systematic review of available scientific literature developed by the technical contributors, led to the development of three Key Messages. Because previous National Climate Assessments did not have a chapter on economics, the team focused on scientific material that was not previously discussed in other chapters of prior Assessments. Based on scoping by the National Climate Assessment Federal Steering Committee, the Economics chapter focused on the economic impact of climate change on the US economy and did not consider economic aspects of potential mitigation policies, which was out of scope. Particular attention was paid to the emerging scientific understanding of inequity of impacts across the country, which informed all Key Messages. Figures were developed by the author team, with support from technical contributors, to highlight key concepts that support the Key Messages. Entries to the tables of example impacts (Table 19.1) were selected, based on an evaluation of their topical importance and breadth of coverage, from a much larger database of more than 300 entries collected by the author team and technical contributors in their review of scientific evidence.

Key Message 19.1

Climate Change Affects the Economy Directly

Description of Evidence Base

There is mounting evidence of climate change impacts on economic costs. This literature requires multi-disciplinary expertise bridging the physical sciences and economics. Broadly, the approaches to estimating climate impacts include biophysical process models, structural economic models, statistical or empirical methods, and hybrid approaches, with each methodology having strengths and weaknesses. A common finding in the above literature[26,38,39,225] is that moderate temperature and/or rainfall are usually beneficial, while cold and heat spells negatively affect a sector, as do droughts and floods. This implies that impacts will vary by 1) the baseline climate, 2) the predicted change, and 3) the vulnerability to such changes. First, colder places might actually benefit from warming as colder temperatures are replaced with moderate ones. Most of the above papers find an asymmetric relationship with regard to temperature, where being too hot is worse than being too cold. Hence, the effect of an increase in extreme heat is the dominant driver for most places in the US leading to a net loss. Second, predicted climate change is not uniform around the world, and higher latitudes (farther removed from the equator) are predicted to see higher warming. Third, vulnerabilities vary significantly across groups; for example, the sensitivity to extreme heat is larger in cold places,[226] and poorer places tend to have higher mortality effects of hotter temperatures.[7]

The literature addresses adaptation either by assessing it directly or assuming results are inclusive of adaptive responses.[7] Examples of directly assessing adaptation include study of the development and penetration of air-conditioning to reduce future temperature-related mortality,[38] the use of drought-tolerant crop varieties to limit the impact of some historical climate events,[161] and the building of seawalls and nourishment of beaches to protect infrastructure and ecosystems from sea level rise.[40] Research often assumes optimal adaptation, but some studies have considered partial adaptation to be more reflective of observed reality.[227]

Major Uncertainties and Research Gaps

A major source of uncertainty in estimates of climate change's economic impacts is representing complex interactions among physical, natural, and social systems. There are a number of critiques of the existing literature but also many important advances. Major uncertainties arise around unmeasured impacts, damages due to non-gradual weather or climate changes, interactions between regions and sectors, projections of population and income growth and technological change, risk aversion, distributional effects, and accounting for adaptation processes and costs. Improving the robustness of economic impact estimates is an active area of research. Scientific advancements in the last decade (National Academies of Sciences, Engineering, Medicine 2017[200] and others) have improved estimates of economic impacts, as well as our understanding of key uncertainties.

One point of uncertainty regards the shape or functional form of the climate damage function. While many empirical studies have found that the increase in global, regional, and sectoral damages as the climate warms can be approximated by a quadratic damage function,[15,47,228] disagreement remains, particularly for higher temperatures. Several studies (Nordhaus 2019; Dietz et al. 2021; Kemp et al. 2022;[229,230,231] see also Dietz et al. 2022[232] reply to comments by Keen et al. 2022[233]) argue that the damage function should become substantially steeper at higher levels of warming.

Damage projections in many sectors do not fully account for expected reductions in future vulnerabilities, for example, as has been observed in the past for temperature-related mortality.[7,38] More study of how the relationship between sensitivity of impact sectors (such as agricultural yields, mortality, or energy consumption) to weather fluctuations and income has changed over time may improve this area of research, as it remains unknown whether confounding factors influence cross-sectional comparisons sometimes used to estimate patterns of adaptation. Damage projections also rely on projections of future population, income, and technology, which are themselves uncertain.

Description of Confidence and Likelihood

There is *high confidence* that climate change will directly affect the economy and that impacts will be unevenly distributed, because numerous information sources document these results across many sectors, and studies of the same outcomes generally agree on the sign and magnitude of these impacts. Many findings are replicated by distinct author teams. Furthermore, insights from biology and physiology, derived from experimental and/or observational data, often support econometric findings. However, the changes in the primary drivers of some of these impacts have complex patterns (e.g., wildfires, floods, drought, hurricanes), while some regions or impact categories may see benefits from warming (e.g., avoided heating expenditures). Therefore, taken together, the finding regarding the substantial cost of these impacts is deemed only *likely*. This same complexity supports the finding of unequal distribution of impacts, so that finding is deemed *very likely*. This unequal distribution is a direct consequence of the different baseline climate (known by looking at current climate), different amount of warming (consistent finding in climate models), and different underlying vulnerabilities due to social determinants such as sensitivity and adaptive capacity. The finding that currently warm places are more negatively impacted by additional warming than colder places is widely supported and garners *high confidence*. Similarly, the fact that vulnerabilities vary by income and education has also been repeatedly observed. Neither point is controversial in the literature.

Given the breadth of approaches to analyzing adaptation, the literature is more varied in conclusions drawn regarding the level of risk that adaptation is expected to ameliorate, the cost of the adaptation actions, and the likelihood that these adaptation actions will actually be implemented. Future innovations may reduce the costs of existing adaptation technologies, or they may result in entirely new technologies. However, some adaptation challenges have proven difficult to overcome,[162] and, ultimately, success is uncertain and there do not exist established approaches for forecasting these innovations. Furthermore, public efforts to adapt to the climate sometimes have perverse outcomes, and it is unclear that similar efforts will be dramatically more successful in the future. For example, in the United States, public provision of both crop insurance subsidies and disaster aid have been estimated to increase vulnerability to extreme weather.[76,199] For all of these reasons, there is only *medium confidence* in findings regarding adaptation.

Key Message 19.2

Markets and Budgets Respond to Climate Change

Description of Evidence Base

Multiple lines of evidence, including theoretical and empirical analyses, demonstrate effects of anticipated climate risks on financial markets. For example, anticipated increases in flood risks due to sea level rise reduce the prices of vulnerable coastal properties[57,101,103] and the prices of long-term bonds issued by vulnerable municipalities.[52,119] These effects have increased over time, coinciding with increasing investor attention to climate change.[57,119,234] Emerging evidence demonstrates potential sources of market inefficiencies due to government policies. For example, existing securitization programs by government-sponsored enterprises, such as Fannie Mae and Freddie Mac, unintentionally encourage banks to issue mortgage loans to properties that are exposed to hurricane risks.[209]

For public budgets, adverse fiscal impacts of more frequent and intense natural disasters are well established. Hurricanes increase public expenditure requirements for healthcare and other programs,[54,132] decrease local tax revenues,[100] and increase municipal borrowing costs.[100] Wildfires have similarly been shown to increase public expenditures on fire suppression and other programs.[53,68,135,192,235,236,237] Evidence on natural disaster impacts on tax revenues is mixed across event types and levels of government (e.g., Liao and Kousky 2022[53]) find positive local revenue impacts of wildfires in California, due to a unique state law that freezes property assessments for taxes until a sale, and Miao et al. (2018)[163] fail to detect significant tax revenue impacts of disasters at the state level). Certain climate impacts may also have partial fiscal benefits, although the evidence is less strong (e.g., EPA 2017;[164] Barrage 2023[68]). However, the same evidence base also suggests negative *net* impacts. For example, Liao and Kousky (2022)[53] estimate large increases in the probability of municipal deficits as a result of wildfire events. Conceptually, disasters such as hurricanes and flooding can also have adverse impacts on tax bases, such as through negative effects on economic growth[51,65,101] and property values.[109,123,131] Finally, the literature documents other fiscal climate costs, such as from infrastructure,[164] the Endangered Species Act,[136] and increasing exposure to flood risk in the balance sheets of financial institutions[208] and government-sponsored enterprises.[209]

For insurance, private markets are important for financial resilience and climate adaptation, but these markets may be stressed by climate change. For example, it is well understood that as climate risks grow, it is increasingly difficult for insurers to offer policies at rates that both reflect risks accurately and that consumers are able and willing to pay, leading to a growing disaster insurance gap (e.g., Issler et al. 2020;[238] Netusil et al. 2021;[239] Kousky 2022[113]). Current risk and, thus, insurance pricing systems may become outdated with changing climatic conditions (e.g., GAO 2021[240]). Evidence suggests that households and businesses

with insurance tend to recover better and faster from disasters (reviewed in Kousky 2019,[114] also Billings et al. 2022[85]).

There is growing evidence that global supply chains can transfer, amplify, or reduce the direct impacts of climate change. Multiple studies have documented that climate events in other countries impact trade with the United States, which in turn affects US domestic market conditions.[110,153,154] A smaller number of studies have identified ways that climate change also causes physical events that impact entire regions, generating costs that can be amplified by production networks.[155,241] It is theoretically well understood that flexible supply chain networks can also enable adaptation to climate change by enabling geographic diversification,[156] although there is not a large body of empirical evidence to demonstrate how this occurs in practice.

Major Uncertainties and Research Gaps

There is considerable uncertainty regarding the estimated effects of climate risk exposure on asset values. For example, estimates of the effect of sea level rise risk on coastal real estate prices vary from as large as –20%[57] to zero.[211] There is also substantial uncertainty about the extent of exposure of financial institutions to climate-related risks.[205] More research would be needed to understand how climate risks affect prices and quantities in debt markets, especially the mortgage market and mortgage-backed security market, and to understand the potential sources of market inefficiencies in pricing and allocating climate risks.

For public budgets, while evidence suggests that many public program costs may be affected by climate change, many of these impacts remain unquantified (e.g., law enforcement and military expenditure changes due to potential increases in crime and international conflict, respectively). Research is also limited on interactions between different climate impacts, such as on migration and fiscal outcomes. For both public budgets and insurance markets, policy uncertainty and uncertainty over adaptation compound the difficulty in projecting climate impacts.

Description of Confidence and Likelihood

There is evidence of market responses to climate change, although the literature on this topic varies in terms of estimates of the magnitude and timing of the response, which leads to a determination of *medium confidence* for this finding. However, climate risk factors are *very likely* to be an important driver of asset values in the future. There is already a significant body of research documenting the capitalization of weather-related risks into the prices of durable assets (real estate, stocks, long-term bonds, etc.), including a growing number of papers finding a reflection of the assets' exposure to future climate risks (e.g., sea level rise, flooding, wildfires, or anticipated carbon policies), leading to a determination that this linkage is *very likely*, although the magnitude varies and estimates of how price changes will unfold over time are uncertain. The literature on this is robust enough to warrant *high confidence*. There is *high confidence* that climate change will stress insurance systems and public budgets that were designed before global warming. This is supported by a large academic literature that considers direct effects of climate change on insured assets such as crops and flood-prone homes, direct effects on publicly funded disaster assistance, and indirect effects on healthcare utilization and social safety net programs. There is also research confirming negative impacts on municipal budgets from natural disasters and projected losses to other public sector budgets. In addition, there is mounting observational evidence of climate stress already impacting markets in certain regions of the country such as Louisiana, Florida, Texas, and California. There is *medium confidence* that trade and economic growth are both *likely* to be impacted by climate changes and by the policy responses designed to mitigate climate change. There is broad agreement that climate change will affect trade, but the magnitude and structure of those changes are complex and not fully understood. Similarly, many studies find that climate change affects economic growth, but there is substantial variation in quantitative results depending on which methods and data are used.

Key Message 19.3

Economic Opportunities for Households, Businesses, and Institutions Will Change

Description of Evidence Base

Substantial literature supports the conclusion that climate change will impose new costs on households and businesses.[15,84,157] In particular, research has focused on income,[15,31,157,166,242,243,244] employment,[4,39,49,167] and changes in real estate value.[57,101,103,105,211] Businesses face increased costs in a variety of areas. These costs include reduced productivity due to heatwaves, lower demand for outdoor activity at more distant locations due to wildfire smoke, supply chain disruption due to hydrologic extreme events (e.g., tropical cyclones in Asia, where semiconductor manufacturing is concentrated), property damage and business interruption losses from weather-related extremes,[245,246] and reduced foreign demand for American products.[5,84,156]

Literature also supports the fact that it is possible to reduce the societal cost of extreme climate-related events through investments in hazard mitigation,[3,76,247] including updated building codes[192,193,194,248,249] and public provision of better climate-risk information, such as flood risk disclosures.[195,250] Research has also shown that existing and new programs and activities associated with public and private institutions will need to play a role in helping to mitigate and adapt to climate change.[52,53,54,68,100,128,135,163] Household financial preparedness and specialized financial instruments[198] can also play a role in reducing losses from climate extremes. While insurance against natural disasters can financially protect households and businesses, these markets are themselves being stressed by climate change, with much natural disaster coverage now offered through fully or quasi-public programs.[113] It remains the case that those most in need of the financial protection of insurance are least able to afford it. There is strong evidence that public healthcare and social support programs can reduce climate vulnerability in certain settings.[190,191]

Major Uncertainties and Research Gaps

It is challenging to anticipate all the ways that households, businesses, and institutions will change in the face of a wide range of climate impacts; continued research on observed and projected responses to climate changes will refine and improve quantitative estimates of the implications of these changes. In particular, systemic risks have proven more difficult to conceptualize and model, and while they could be extremely costly, they have received less research attention. We also have limited understanding of nonlinearities in the costs or threshold effects that may materialize in both natural and human systems. Public programs can potentially moderate the inequality of climate impacts in important ways, but more research would be required to identify cost-effective and scalable strategies.[251] There are also uncertainties regarding how to target healthcare and other social support programs to achieve the largest net benefits.

Description of Confidence and Likelihood

There is a large literature base and high agreement regarding the variety of new or higher costs of climate change, leading to the finding of *very likely* and *high confidence* for this statement. There is less literature available characterizing the alteration of the economic landscape due to climate change, and while new risks predominate, there is a subset of papers that discuss the potential for new opportunities that business can take advantage of: this leads to the *likely* and *medium confidence* finding. Similarly, there is less literature regarding the response of institutions to changing climate conditions, leading to a *medium confidence* finding. There is extensive literature and a high level of agreement that private and public investments in adaptation and mitigation can reduce household and business costs, leading to the assessment of *high confidence*.

Introduction

Social Systems Are Where Climate Change Is Created and Experienced

Climate change is a result of human behavior and has differentiated effects on communities and peoples around the United States and the globe. It is inextricably tied to a history of human development and decision-making—from individuals to organizations to entire societies. For this reason, we cannot fully understand or respond to current or future changes in climate without understanding this history of human organization—that is, without understanding social systems.

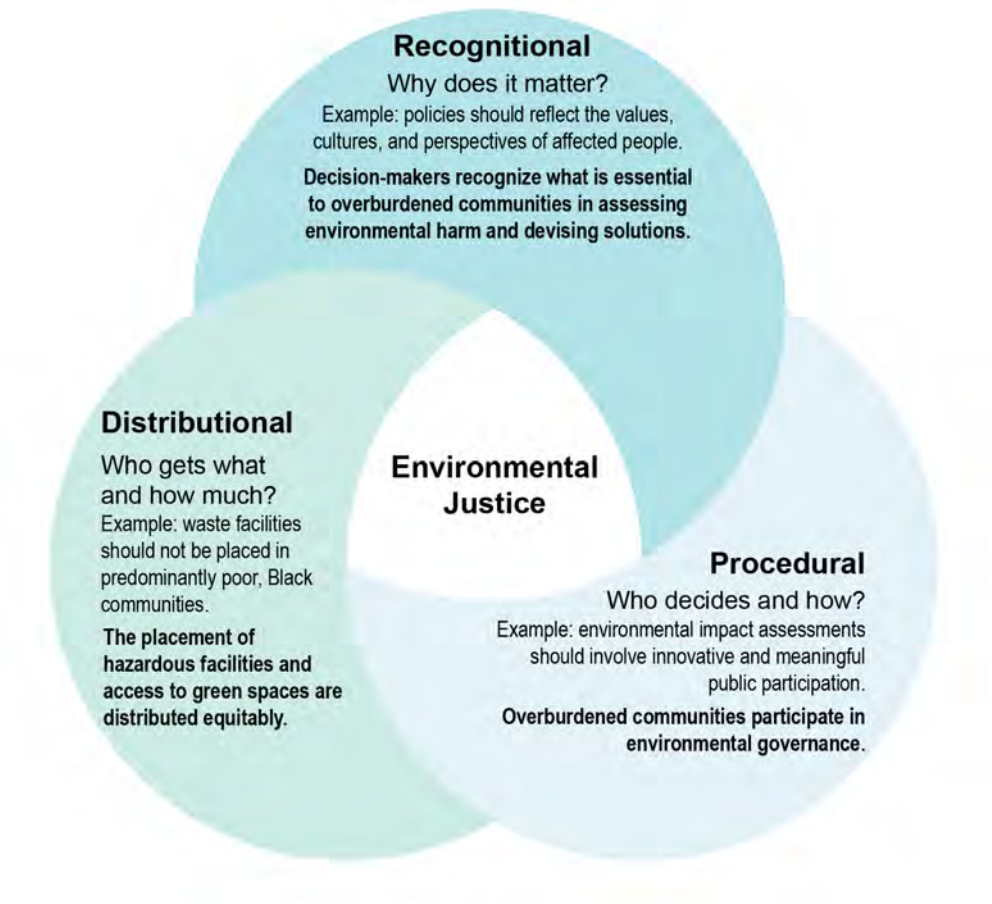
Social systems create and reproduce the assumptions that we—individuals and institutions—act on when making decisions about climate change over time and space. This might include what a given community considers sacred or taboo, or how we speak of and conceptualize environmental problems. Lack of rain, for example, may be conceptualized differently by scientists, farmers, government agencies, and land developers; and what is identified as cause for action (or sacrifice) may change depending on whether growing food is experienced as sacred, a national security issue, or an economic input.

Critically, social systems define who is seen as deserving of local, state, and federal interventions to address climate impacts. For example, they determine which neighborhoods receive hazard mitigation investment or post-disaster recovery aid. Through complex interactions, conscious and unconscious tendencies and biases, and visible and invisible social rules, social systems distribute climate risks and benefits; they also create the opportunities for climate adaptations and climate mitigation to be envisioned and acted upon.

There is growing evidence that understanding social systems is an integral part of climate science and climate solutions-making, including identifying links among adaptation, mitigation, and climate justice. The importance of social science and humanities research on climate change has been made clear by contributions across many fields, including but not limited to anthropology, communication, ethnic studies, geography, history, linguistics, philosophy, political science, psychology, public policy and administration, religious studies, and sociology.

This chapter highlights and summarizes contributions to climate change science from across the social sciences. It explains that social systems give rise to greenhouse gas emissions and distribute the risks and benefits of industrialization and climate change (KM 20.1). The chapter also explains how knowledge, culture, ethics, communication, and decision-making shape engagement with and responses to climate change (KM 20.2), as well as how climate adaptation and mitigation processes, such as human migration and transitions away from fossil fuels, may be just or unjust (KM 20.3). Central to this chapter is an explanation of how social systems inequitably distribute harm to BIPOC (Black, Indigenous, and People of Color), low-income, and rural communities; women and gender minorities; and other racialized or overburdened peoples. Key to this explanation are the concepts of environmental justice and environmental injustice. Environmental justice has three primary dimensions: recognitional, distributional, and procedural (Figure 20.1). This chapter uses these three dimensions to explore whether the actions taken to create, mitigate, or adapt to climate change are expected to produce just or unjust outcomes.

Three Dimensions of Environmental Justice



Environmental justice requires three dimensions: recognitional, distributional, and procedural justice.

Figure 20.1. These three dimensions of justice are based on a framework originally summarized by the "father of environmental justice," Robert Bullard,[1] who pointed to the "ethical and political questions of 'who gets what, why, and in what amounts?'" Commitments to each dimension are essential to achieving environmental justice, and each dimension can influence the others.[2,3,4] Figure credit: Puget Sound Partnership, Citizen Potawatomi Nation, and University of Michigan.

Key Message 20.1

Social Systems Are Changing the Climate and Distributing Its Impacts Inequitably

Social systems are changing the climate (*very high confidence*). Societal characteristics and processes shape greenhouse gas (GHG) emissions, primarily through the burning of fossil fuels (*very high confidence*). Social systems also inequitably distribute the benefits of energy consumption and the impacts of GHG emissions and climate change (*high confidence*). Governance is a critical process that distributes these impacts (*very high confidence*) and provides access to adaptation (*medium confidence*).

Emissions Are a Consequence of Social Systems

Social systems produce and distribute climate change and its impacts through mechanisms such as economic growth, population dynamics, social and economic inequities, governance, militarization, and world-economic integration (KM 2.1).[5,6,7,8] Greenhouse gas (GHG) emissions, and especially carbon emissions, are a significant and measurable outcome of energy use that leads directly to climate change (KM 3.1), the impacts of which are largely determined by social systems.[9,10,11,12] The relationships between emissions and standards of living in higher-income and lower-income nations exemplify unequal access to the benefits of industrialization and world-economic integration[13,14,15,16,17] and highlight different responsibilities for the human drivers of climate change.[17,18,19,20] Industrial processes over the past two centuries produced GHG emissions and improved quality of life, but these benefits have not been equitably distributed.[21,22,23,24] However, some societies (e.g., countries or smaller subnational units) have achieved high levels of human well-being, such as increased average life expectancy or perceived high quality of life, without consuming substantial amounts of fossil fuels per capita.[25,26,27,28,29,30,31,32,33]

Relationships between emissions and other social features are evident across time and space and at different scales. National-level carbon emissions are strongly associated with economic growth.[34,35,36,37,38,39,40,41] Using regression analysis, researchers have also identified structural factors that shape the relationship between economic growth and carbon emissions. For example, the relationship between emissions and economic growth is stronger for nations with greater levels of income and wealth inequality or whose economies are more reliant on natural resource exports.[42,43,44,45,46,47] All else being equal, nations with larger and more capital-intensive militaries have higher emissions,[48,49,50,51] most notably the United States.[52,53,54] Conversely, nations with a stronger environmental civil society or more gender equality experience a decrease in the relationship between economic growth and emissions.[55,56,57]

Carbon emissions, overall, have a positive association with population size.[39,58,59,60] Population growth is higher in lower-income nations than in higher-income nations and contributes to rising energy consumption and carbon emissions, although empirical research also suggests that such population growth threatens global climate stability less than higher-income nations' carbon-intensive economic activities.[61,62]

Subnational analyses show that increases in emissions over time are moderately lower in US states with a greater concentration of environmental nongovernmental organizations[63] and in US states with legislators exhibiting strong environmental records.[64] This research points to the role of governance and related institutional arrangements in mitigating emissions.

Climate Impacts Are Distributed Unevenly

While all people are exposed to human-caused climate change stemming from GHG emissions, social systems shape the degree of exposure and distribute climate impacts across people and places over time (KMs 4.2, 5.2, 11.2, 15.2, 23.1, 31.2). *Exposure* and *impact* are differentiated in the social science and climate change literature. As an example, flood exposure is understood as the probability of water inundation and risk to infrastructure, whereas flood impacts could be the displacement and housing insecurity that result from preexisting conditions interacting with the inundation or high water.[65] Individuals and communities that have lived at the margins of, or have been purposely excluded from the benefits of, industrialization have a greater probability of exposure to pollution and negative environmental impacts.[66] For example, in the United States, Black and BIPOC individuals and communities, members of low-income households, immigrants with limited English proficiency, unhoused individuals,[67,68,69] rural communities,[70,71,72,73] and agricultural workers are disproportionately impacted by environmental hazards[66,74] and climate change (Figures 4.15, 4.16, 18.2; KMs 4.2, 11.2, 14.3, 15.2). The convergence of exclusion, exposure, and impacts places unequal burdens on these individuals and communities, sometimes referred to as overburdened communities.

The burdens of climate change and social inequity become acute during disaster events[71,75,76,77,78,79] and can be exacerbated by governance decisions.[80] Hurricanes Maria and Harvey, for example, had disproportionate impacts on minority households, renters, multifamily households, and low-income families due in part to governance decisions related to aid distribution and documentation requirements (Box 4.2; KMs 23.1, 23.5; Figure 26.3). In this case, application and appeals processes for disaster assistance required documentation that some residents did not have or required the navigation of complex aid structures that some people could not successfully find their way through.[81] This left those same families and communities struggling to meet basic needs in the immediate aftermath[82,83] and unable to access funding for rebuilding. These obstacles to recovery can have long-term generational effects related to the loss of savings, housing insecurity, and displacement. For example, people who migrated to California from the southern Midwest during the Great Depression fared worse than native Californians for at least a generation.[84] The absence of data and data collection, such as demographic and hazard data, compounds the challenges of equitable governance during disasters. Data limitations in territories, for example, have direct impacts on the availability of resources and the visibility of at-risk populations.[85,86,87]

Policy processes and governance also influence the formation of socioecological landscapes before and after climate change–related disasters.[88,89,90] For example, the use of a cost–benefit analysis for the allocation of hazard mitigation funding, and disaster-related assistance for rebuilding, gives priority to areas of denser population and higher-value housing stock.[91] Pre-event social vulnerabilities, such as a lack of clear title for real estate, lack of financial capital, and subpar housing leave some populations at greater risk of negative impacts following a disaster.[81] For example, a family without clear title may have a more difficult time proving home ownership in order to access federal rebuilding assistance, and subpar housing may be more difficult to insure and repair.

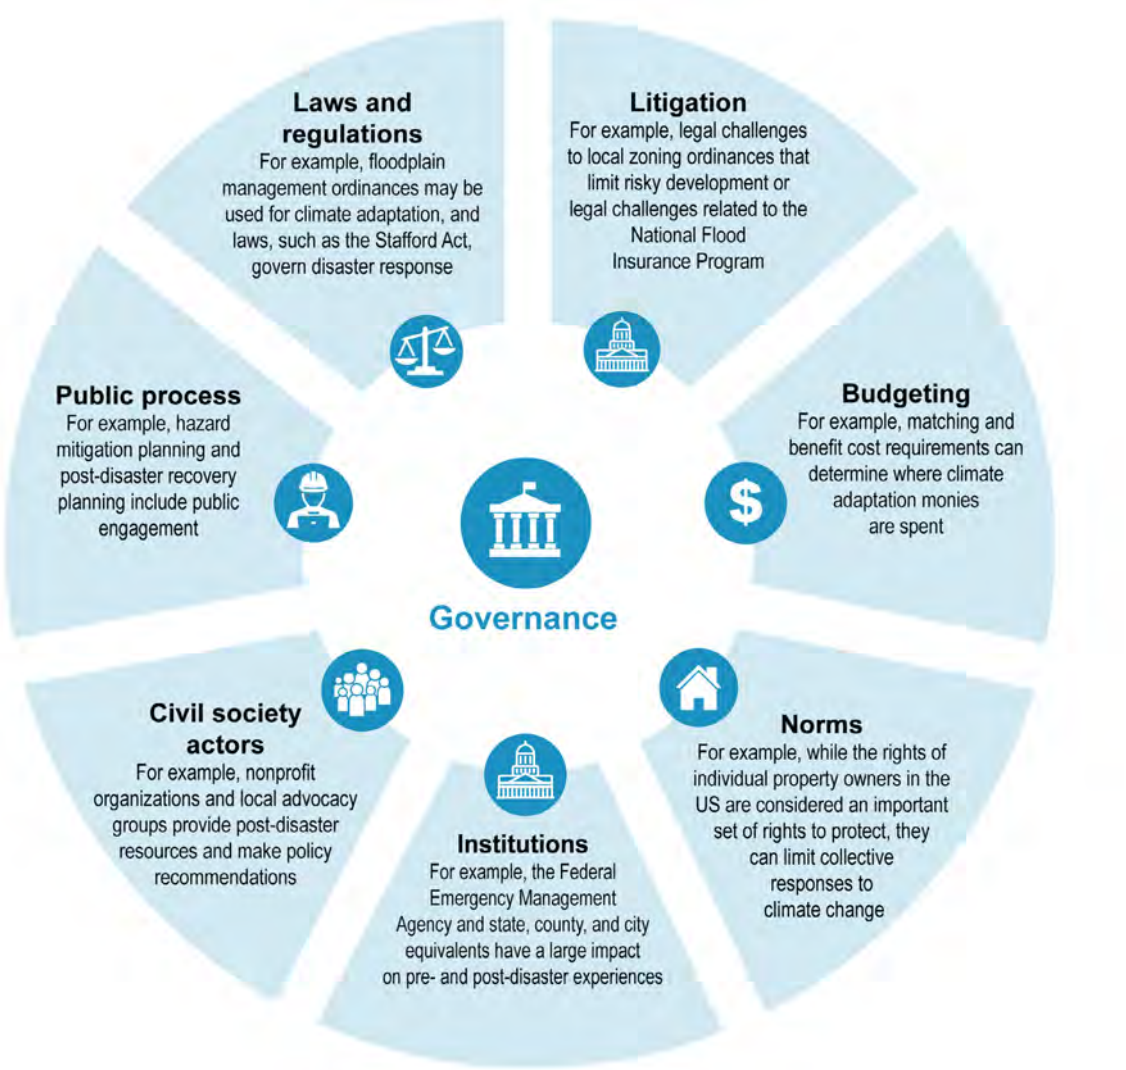
Structural Inequalities Affect Outcomes

Even when all citizens are treated the same under the law, differential outcomes may result if the law ignores structural inequalities.[92,93] For example, when aid is delayed or not readily available following a disaster, low-income individuals and families may lack access to food and shelter even when those costs will be reimbursed. Under these same conditions, middle- or high-income individuals and families often have greater access to credit and other financial resources that allow them to spend money now and then wait for reimbursement.[94]

All levels of government (including federal, state, and county) shape the impacts of climate change and are impacted by a complex variety of social systems (Figure 20.2). Inclusive, rapid governance responses

that promote adaptation and mitigation are challenging to create,[95,96] in part because governmental institutions have difficulty innovating quickly.[97] Conditions that create the disaster impacts described above occur over decades or centuries, while governance responses to these impacts are asked to be created in far less time in order to be effective. The United States' three-branch system of government was designed to prevent those in power from taking quick action and harming those in the minority.[98] Stemming from this arrangement, a key challenge for climate adaptation and mitigation is how to react to quickly changing circumstances given the slow pace at which legislative action and other forms of governance occur (KMs 4.3, 31.3).

Climate Change Governance



Climate change governance is complex and multifaceted.

Figure 20.2. This figure recognizes the complex interaction of multiple social systems that give rise to governance. Climate change impacts, and the impacts of adaptation and mitigation strategies, will all be mediated by governance decisions and actions. Understanding this complex interplay allows the social scientists who study climate change to make predictions regarding climate impacts and to assess where governance systems are expected to produce climate justice or injustice. Figure credit: Jacksonville State University.

One example of adaptive governance in the face of climate risk occurred in Tulsa, Oklahoma, where a broad coalition of civil society and local, state, and federal government actors came together to address flood risk and to create structures and organizations that continue to drive risk reduction for all hazards. Tulsa was the most frequently flooded city in the United States from the 1960s through the 1980s.[99] Almost 40 years ago, a coalition of concerned citizens and flood victims brought pressure to bear on city hall to address the problem. This coalition was eventually joined by government and elected officials and supported by federal partners, which led to a comprehensive floodplain management approach that has served as a model for other cities.[100] The city was able to enact stricter land-use regulations and draw on federal incentives through the Community Rating System to garner public and political support.[101]

Key Message 20.2

Social Systems Structure How People Know and Communicate About Climate Change

People's histories, educations, cultures, and ethics determine how they understand and experience climate change (*high confidence*). These knowledges take multiple forms (*high confidence*) and generate diverse approaches to climate adaptation and mitigation (*medium confidence*). Engagement across communities that builds clear objectives and benchmarks has been shown to produce more desired outcomes (*medium confidence*). Effective engagement is challenging due in part to the complexity and uncertainty associated with climate science and politics (*high confidence*). Including community perspectives and multiple forms of knowledge in climate discussions and decision-making helps promote justice (*medium confidence*).

How People Know About Climate Change

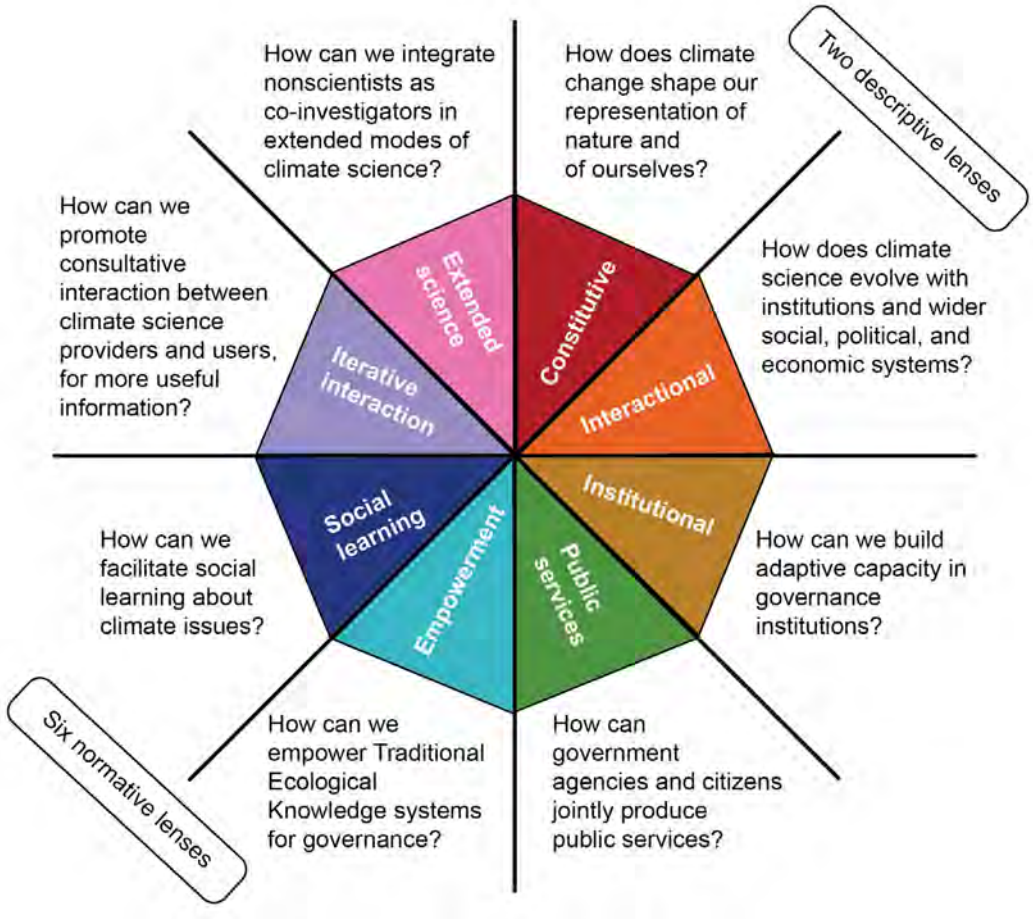
Researchers in the social sciences and humanities have studied the ways in which people and groups learn about and understand human–nature interactions, including climate change.[102,103,104] Epistemology is the name for the study of how people develop knowledge. For both scientists and nonscientists, epistemological assumptions influence an understanding of what the drivers of climate change are, what kinds of evidence matter, and what are seen as appropriate and ethical responses to its risks and impacts.[105,106,107,108,109,110,111,112] For example, climate modelers may use computer models to predict the thinning and reduction of Arctic Sea ice in order to produce more accurate maps and forecasts. Indigenous Arctic walrus hunters might instead draw on their experiences and observations to better understand the complex interconnections among ice thickness and timing, ocean currents, walrus behavior, prey dynamics, accessibility of hunting locations, travel safety, and food security to make decisions about the long-term sustainability and health of their community,[113] which may conceptually include both walruses and people.

Recognizing that knowledge emerges out of different histories and traditions can lead to new insights regarding mitigation and adaptation (Box 23.1).[114,115,116,117,118,119,120] For climate scientists, the principal driver of climate change is understood to be GHG emissions.[121] From this perspective, climate mitigation involves reducing emissions. In contrast, people who have been excluded from the benefits of industrialization, or disproportionately harmed by industrial processes, might see the principal driver of climate change as the social systems and ethical arrangements that allowed for the simultaneous exploitation of land, animals, and peoples.[77,119,122,123,124,125,126,127,128] If climate change is understood as an outcome of socioeconomic and ethical arrangements that resulted in exploitation and discrimination, then reexamining those arrangements also

becomes necessary.[129,130,131,132,133,134,135] Most often these insights are not contradictory but rather expand the universe of possible solutions for climate adaptation and mitigation.[136,137]

A promising area of research that takes different forms of knowledge seriously is called coproduced or cocreated research (Figure 20.3).[138,139,140] While coproduction is an increasingly widely used term with varied definitions (Figure 20.3), coproduced climate change research projects often integrate community-based insights and solutions to climate change with scientific insights and solutions. Coproduced research often foregrounds nonscientists, such as Indigenous Knowledge holders or multigenerational farming communities, as experts within their own knowledge contexts (KMs 18.3, 31.5). This kind of research can give rise to community-based resilience efforts. Research in the Arctic, for example, has been particularly successful at experimenting with coproduction, especially in integrating Indigenous and Western scientific knowledge bases.[141,142] However, integration can fail if power dynamics, goals, trust, and compensation within research teams and epistemologies are not equitable.[143]

Coproduction in Research



Coproduction is a way forward to include multiple epistemologies, or knowledge traditions, but must be defined to be productive.

Figure 20.3. This figure demonstrates the diverse approaches to coproduction and focuses on the need to define what a research team means when seeking to do a coproduced research project. The two items in the top right quadrant are descriptive lenses, while the other six are normative lenses. Adapted with permission from Bremer and Meisch 2017.[138]

One important consequence of different epistemological assumptions is that different people and groups perceive climate change risks and possible solutions in widely different, often compatible, but sometimes conflicting, ways.[144,145] For example, the politicization of climate change in the US helps to explain differences in public perceptions of severity and concern as a function of demographic factors such as gender and political ideology.[146,147] In this case, women and liberal-identifying individuals report relatively higher levels of concern and support for mitigative action and policy. In contrast, climate change is a relatively less polarizing issue among racial and ethnic minorities as well as socioeconomically disadvantaged groups compared to White populations and higher-income groups.[148] In part, beliefs and concerns about climate change have been shaped by well-documented, intentional efforts by industry groups supportive of the continued use and promotion of fossil fuels to misrepresent the uncertainty and knowledge about climate change and downplay the risks to society.[149,150,151,152]

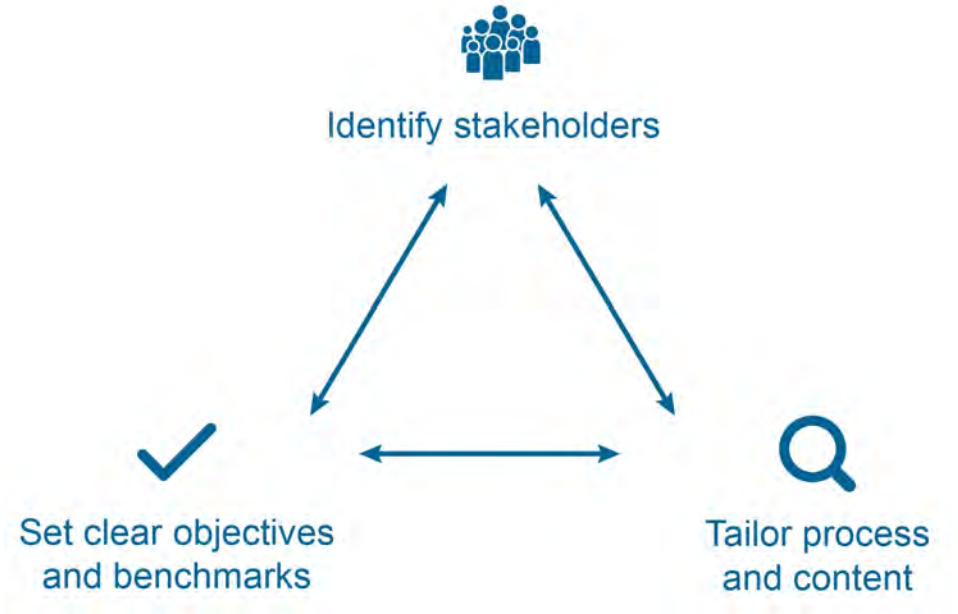
Processes for Promoting More Effective Climate Change Engagement Efforts

As suggested above, diverse communities have distinct knowledge traditions within which people interpret climate change. These diverse communities also engage with climate science and information in different social and cultural settings. There have been numerous explicit efforts over the past few decades to build greater levels of public engagement with the issue of climate change and climate science. These climate change engagement efforts have taken many forms, including traditional expert-to-public communication products (e.g., USGCRP National Climate Assessments, documentaries, journalism) and more participatory activities (e.g., public art installations, town meetings, deliberative democracy forums).[153] These efforts occur in both formal (e.g., K–12 and college classrooms) and informal (e.g., zoos, museums) settings and are sometimes tied to intentional educational activities; however, much climate change engagement occurs outside formal classroom settings.

Significant efforts and resources have been put into improving the effectiveness and accessibility of climate change information and engagement activities over the past decade. One outcome of these efforts has been collective learning regarding processes and actions that improve effectiveness of climate change engagement efforts. We describe some of these insights below.

First, establishing clear, measurable objectives with well-defined benchmarks or desired outcomes leads to more effective communication products and processes (Figure 20.4); bringing key stakeholders into the process at this early stage can improve effectiveness.

Successful Climate Engagement



A simple three-step process of communication can improve climate change engagement with diverse stakeholders.

Figure 20.4. Simple changes can help facilitate communication about climate change. Identifying the stakeholders, tailoring the process of communication and knowledge creation, and setting clear objectives for everyone involved has been shown to be an effective process. Figure credit: Rutgers University, University of Massachusetts Amherst, and Oregon State University–Cascades.

Second, to inform real-world decision-making, information needs to be calibrated to the needs of target audiences;[154,155] importantly, communicating relevant information sometimes involves translating science into accessible and actionable language, whereas in other cases it involves incorporating diverse forms of knowledge into communications products and efforts. For example, farmers and forest owners often have different informational needs with respect to climate change impacts and implications for management: whereas farmers may be most interested in seasonal forecasts or timescales of a few years, forest owners may be more interested in projections of trends for the next few decades. Climate change communicators must know—or put in place processes to uncover—the needs and epistemologies of their intended audiences.

Third, including intended target audiences throughout the process of developing communication products[156] both promotes procedural justice and increases the likelihood that such efforts meet shared goals.[157,158,159] In parallel, communicators—including formal and informal science educators—may in some cases better meet their own and audiences' goals via setting- and audience-specific trainings that provide a strong grounding in both climate science and effective communication, such as the National Network for Ocean and Climate Change Interpretation.[160,161]

Fourth, efforts that have been successful in engaging people on climate change across existing ideological and cultural divides generally do so by addressing the things people care about most, such as livelihoods, homes, investments, local communities, and family.[154,162,163] It is not always necessary to connect relevant impacts to climate change to motivate action, and doing so can sometimes backfire; for example, providing

environmental-benefit information (green labels) on energy-efficient products decreased the chances of their purchase by conservatives relative to when no label was provided.[164]

Fifth, engagement outcomes also strongly reflect the relationships and levels of trust between intended audiences and messengers. The use of trusted messengers increases acceptance and use of climate change risk information. For example, parents, teachers, peers, and scientists are considered trusted messengers for youth audiences, and the use of targeted messages and trusted messengers can increase engagement even among adversarial audiences;[165,166] similarly, experimental research has found that classroom-based climate change curricula offered to school-aged children can influence the climate change beliefs and engagement of adults who interact with those children.[167]

Sixth, pervasive uncertainty surrounding climate change (including public uncertainty) continues to be a major challenge to communication, but there is evidence that certain practices can help people understand the likelihood and magnitude of expected or possible changes and their implications for decision-making.[168] For science communicators, these include avoiding unfamiliar probabilistic statements and combining verbal and numerical assessments of likelihood—for example, when describing an outcome as "unlikely," simultaneously providing the corresponding numerical assessment of "0%–33%" probability;[169] using visualizations to show probabilistic information;[170] transparently discussing possible ranges for future outcomes or impacts, including both worst- and best-case scenarios;[171] and focusing attention on the types and magnitude of expected impacts rather than on when, specifically, those impacts might occur.[163] Commonly used technical phrases such as "1-in-1,000-year event" can often lead to mistaken beliefs or expectations about the probability of repeat occurrences of disasters such as flooding or wildfire.

Implications of Engagement Efforts for Decision-Making and Justice

A growing evidence base identifies how and when engagement and communication can lead to changes in climate decision-making.[114,172,173,174] Some work suggests that such efforts can, over time, move people from unawareness of the issue to initial awareness to more active and involved engagement at the personal and collective levels.[175] Although many engagement efforts aim to increase knowledge about climate change and climate science or shift attitudes, some efforts are more directly aimed at supporting mitigative and/or adaptive behavior change related to climate change. For example, extensive work on social norms messaging—which communicates information about the behavior of others, or expectations of behavior, and provides cues and social pressure—finds evidence that such information can influence several climate change-relevant behaviors, including household energy consumption.[176]

Efforts to engage diverse groups and communities with the issue of climate change also have critical upstream and downstream justice-related implications. For example, engagement activities or processes that actively work to include diverse stakeholders throughout the knowledge creation and/or application process (in, for example, setting objectives, developing content, and drawing implications) are more procedurally just than top-down efforts that simply attempt to provide actionable information to those groups.[177] Recognitional justice is similarly promoted by inclusive engagement efforts and inhibited when diverse, climate-impacted communities or groups are excluded from the process of setting engagement and/or knowledge-creation objectives. Thus, efforts to engage diverse publics, and the epistemologies and struggles they inhabit, within climate change decision-making are a key mechanism through which justice-related outcomes or objectives can be either realized or thwarted, intentionally or unintentionally.

Key Message 20.3

Climate Justice Is Possible If Processes like Migration and Energy Transitions Are Equitable

Climate justice—the recognition of diverse values and past harms, equitable distribution of benefits and risks, and the procedural inclusion of affected communities in decision-making processes—is possible (*medium confidence*). Complex social processes such as human migration affect climate inequities (*medium confidence*). Climate justice is also closely related to just transitions (*high confidence*), which involve equitably adapting societies, economies, and energy systems to climate change mitigation strategies and climate impacts (*high confidence*).

Human Migration May Be a Pathway to Climate Justice or Injustice

The concept of climate justice is useful in understanding how the impacts of climate change, and the impacts of climate change mitigation and adaptation, are distributed across communities. Climate justice recognizes that the inequitable distribution of resources and other social and political capital impacts the capacity for adaptation during times of upheaval, including the upheaval created by climate change. Human migration is a complex response to pressures created by social, political, economic, and environmental systems, including climate change.[178,179] The dynamic interactions among climatic changes, market processes, governance decisions, and historical inequity make human migration a critical example of how climate change interacts with preexisting social processes to alleviate or exacerbate inequity (Figure 20.5).

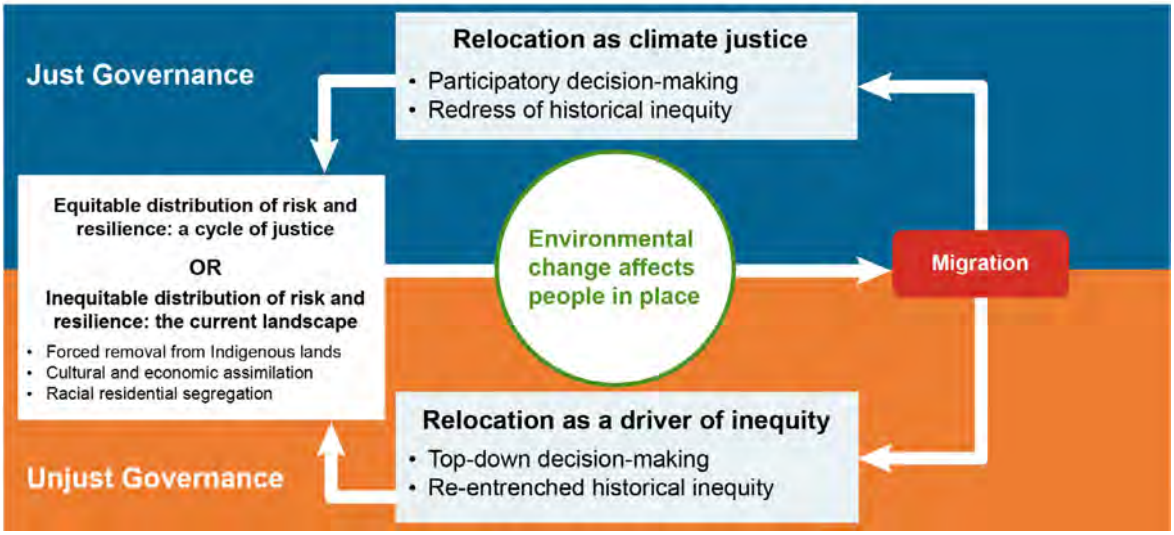
In the United States, climate change–related disasters are not yet a major driver of migration.[180,181] Most counties affected by hurricanes deviate only temporarily from their pre-disaster growth trend, although the demographic composition of affected areas may change.[182,183,184,185] Historically, most communities have adapted to climate hazards by engineering protections and adaptive technologies.[186,187,188] As climate change impacts overwhelm the protective ability of these solutions, as is expected to occur in the future (KM 9.2), communities are expected to adapt by accommodating hazards or by relocating away from hazardous areas.[189,190]

Recent hurricane events illustrate how extreme weather has displaced unprecedented numbers of people, mostly temporarily, and caused billions of dollars in damages.[191,192,193,194,195,196,197,198,199] Tropical storms pose an ongoing threat to about one-fifth of the US population that lives in coastal communities along the Atlantic and Gulf Coasts.[200] Further, every US region experiences climate-related hazards (KMs 21.1, 22.4, 23.3, 24.2, 25.1, 26.1, 27.4, 28.1, 29.2, 30.3). Efforts to predict future migration depend on assumptions about how climate hazards will affect the habitability of places far into the future, mostly informed by models of sea level rise or heat extremes.[201,202] These climate impacts are predicted to unfold gradually and unevenly, producing unpredictable impacts at small temporal and spatial scales. Governance that does or does not anticipate climate hazard events, and does or does not account for past harms, will determine whether migration will exacerbate inequities or offer a pathway toward climate justice (Figure 20.5).

Past experience with weather-related disasters illustrates the complexity of the relationship between environmental change and migration (Figure 20.5). Disasters that destroy housing and infrastructure have the potential to displace people from their homes, neighborhoods, and communities. Yet social systems that govern land and property—such as housing markets, homeowners' insurance, and federal disaster recovery housing assistance—promote in situ housing recovery for most homeowners (but notably not for renters and those with precarious title to property).[203] For example, federal disaster assistance and

private insurance incentivize many homeowners to rebuild in place, a social system that aligns with residents' place attachment.[204,205,206] Homeowners maintain and rebuild their housing to protect its market value and increase its resilience to future hazards.[207] In contrast, historic and ongoing discriminatory real estate practices, such as redlining and predatory lending, sort low-income and BIPOC households into environmentally risky neighborhoods and deteriorated housing[66,208,209] and into rental housing or housing types that are more susceptible to disaster-related damage, such as multiunit buildings and mobile homes.[210,211,212,213,214] The low property values in these neighborhoods and renters' tenuous connection to their homes also make residential mobility after a disaster more likely. For example, homeowners may be unable to repair and rebuild their homes because insurance and disaster recovery assistance align payments with pre-disaster property values, creating large gaps in the ratio of funds to rebuilding costs.[215,216] Rental properties, which house a disproportionate number of low-income and BIPOC households, are rebuilt more slowly than owner-occupied housing, driving up rents and limiting the number of affordable rental units.[203,207,217] Consequently, more residential mobility is observed among renters and those lacking clear title to their property.[182,185,218,219,220] Additionally, upheaval in housing markets after disasters is associated with increases in evictions and gentrification, as real estate speculators buy up deeply discounted properties for development.[221,222,223] Thus, there are multiple housing-related pathways through which low-income and BIPOC households are displaced or compelled to migrate as a result of climate-related disasters. These processes can therefore exacerbate pre-disaster inequalities through unjust governance and unequal distribution of risk and resilience.

Migration and Governance



Social systems create just or unjust conditions that influence migration outcomes.

Figure 20.5. Research shows that social systems exert influence on migration. Historically, forced migration has exacerbated inequities and caused social harm. It is not yet understood how these dynamics will play out under conditions of climate change and whether climate-inflected migration can be a pathway toward climate justice. This figure captures, conceptually, how migration may exacerbate inequity or be a remedy. Figure credit: Oregon State University–Cascades, Brown University, Jacksonville State University, and Puget Sound Partnership.

Current US policies governing relocation away from locations where repeated hazard events have occurred involve home buyout programs. Voluntary homeowner buyout programs have been used as a piecemeal strategy for hazard mitigation, often as part of post-disaster recovery assistance.[224,225,226] However, buyout programs often lack transparency, resulting in public distrust and low participation, as well as

disproportionate participation in low-income and BIPOC communities.[227,228] Buyout programs tend to be pursued in counties with higher property values, more home equity, and higher proportions of White residents, yet within these counties a greater number of buyouts tend to occur in BIPOC neighborhoods, suggesting home buyouts are an inequitable mechanism for moving people out of harm's way (KMs 18.2, 21.3, 22.1).[229] Furthermore, home buyout programs have been deemed inadequate to the scale and complexity of managing relocation away from climate-related hazards.[230] Programs designed to relocate residents out of areas exposed to hazards in a way that promotes climate justice would consider these historical and ongoing social inequities and take steps to mitigate their impact.

Relocation as an outcome of flooding can be prevented or forestalled with the preservation and installation of green infrastructure, such as riparian zones, wetlands, trees, parks, and other green stormwater management systems.[231,232,233,234,235] However, if justice is not taken into consideration, these same adaptation projects that alleviate climate-related displacement can cause the displacement of low-income residents, as property values often rise when improvement and hazard mitigation projects are planned and executed, leading long-time residents to be priced out of the market.[236] Climate adaptations therefore can create social risks similar to those of climate-related disasters.

What Are Just Transitions?

Central to climate justice is the concept of a just transition—or just transitions, as approaches may be diverse and locally specific. The idea of a just transition emerged from labor environmentalism in the 1970s. Labor union leaders recognized the need to support workers who lost their jobs due to stricter environmental policies or whose jobs exposed them to toxic materials.[237] Just transition approaches focused on the creation of green jobs and training workers to fill these jobs. In the past 40 years, the concept of just transitions has broadened and now refers to mitigating and adapting to climate change in a managed process that ensures equitable access to jobs, environmental goods, and quality of life.[238] If efforts are made to shift the economy away from fossil fuel extraction, thus displacing workers in coal, oil, gas, and other energy sectors, job creation and training will continue to be vital components of just transitions. This broader approach to just transitions emphasizes that poor and BIPOC communities that have experienced the brunt of environmental injustices, including both pollution and climate change impacts, are the least responsible for these impacts.[239] Without just transitions, these inequities are expected to be exacerbated as society moves away from fossil fuel extraction, responds to climate adaptation and mitigation processes, and shifts toward a sustainable and green society (KMs 5.3, 14.3).[88,240]

Just transitions recognize the capacity of green infrastructure not only to mitigate hazards, capture carbon, and provide local cooling but also to redress past harms and minimize social inequities. For example, decisions about where to place green infrastructure might take into account legacies of unjust social systems and ongoing social inequality that shape the unequal access of BIPOC and low-income communities to environmental amenities and their overexposure to environmental harms.[241,242,243,244]

The green infrastructure equity index can help provide a more nuanced examination of communities and their access to green space.[245] Not taking into account these forms of justice has been shown to contribute to the uneven distribution of urban green infrastructure.[246] Other examples have shown that using spatial tools and indices examining the built environment that include racial, social, and economic indicators can help us understand the inventory, condition, and distribution of green infrastructure[247] and use that information to promote equity.

Current Policy Creation as Part of Climate Justice

Mitigation and adaptation policies and programs are being implemented at federal, state, and municipal scales in multiple sectors (KMs 31.1, 32.5) and have implications for climate justice (KMs 31.2, 32.4). Both Colorado and California have charged agencies with creating plans to guide their transition away from coal, with a focus on economic diversification, job creation, and workforce training for former coal workers. Colorado's Just Transition Action Plan, approved in 2020, acknowledges a commitment to communities disproportionately impacted by coal power pollution.[248] California's Office of Planning and Research is in the process of creating a Just Transition Roadmap. Executive Order N-79-20, which mandates the roadmap's creation, includes language highlighting the disproportionate impact of coal pollution on low-income and BIPOC communities; however, it is still uncertain whether the roadmap, like Colorado's plan, will be focused on former coal workers.[249]

The Federal Government has also enacted a portfolio of environmental, climate, and economic justice policies that seek to ensure no one is left behind by climate change and energy transformations. These are examples of policies that seek to incorporate climate justice into governance structures. The Justice40 Initiative,[250] a policy that aims to ensure that 40% of the benefits in these investments flow directly to disadvantaged communities, is one example. Other indices and geospatial and measurement tools—such as the Climate and Economic Justice Screening Tool and the National Risk Index—have been developed to gauge whether climate exposures and impacts or the impacts of climate adaptation and mitigation are being distributed equitably. In addition, federal civil rights laws such as Title VI of the Civil Rights Act of 1964,[251] Section 504 of the Rehabilitation Act of 1973,[252] and Section 308 of the Stafford Act[253] are written to ensure that the implementation of environmental, climate, and economic policies do not discriminate against protected classes. The outcomes of these programs and the efficacy of these indices in leading to just and equitable access to resources have yet to be realized or analyzed.

Box 20.1. Quinault Indian Nation Relocation and Sovereignty

The Quinault Indian Reservation, located along the central coast of Washington State, is experiencing an accelerated loss of land caused by sea level rise, flooding, and erosion. To adapt, the Quinault Indian Nation (QIN) is relocating the Quinault Tribal community from their traditional village site, where they have lived and to which they have been tied since time immemorial, to a newly developed site at higher elevation.

Meaningful community engagement throughout relocation decision-making processes facilitates participation that recognizes community values and culture. Community engagement means engagement that involves local experts and nonexperts and allows impacted populations to have decision-making power and consent pathways (KM 16.3). This kind of engagement can be a profound way to incorporate local wisdom and values. Reflecting on possibly relocating, a Quinault Tribal member shared this sentiment: "I've made my life living off of the land and the water, and if it's my turn to give something back, I'll go with it" (interview with community member quoted in Watkinson-Schutten 2022[254]).

While many Indigenous communities are concerned with carrying out plans that consider seven generations into the future, historic US policies imposed on American Indian Tribes and other Indigenous communities have greatly limited Tribal self-determination to conduct long-term planning that allows the Tribe to adapt to changing conditions. Land allotment and assimilation policies that led to the fractionation of lands, for example, impact the available relocation sites that would help QIN adapt to climate change. Reacquiring and consolidating Tribal trust land through buyback programs enhances the adaptive capacity of Tribes experiencing climate change impacts.[254]

Relocation and Tribal Sovereignty

Quinault Indian Nation engaged the full community in its village relocation plan.

Figure 20.6. Community members gather for a ribbon cutting for Quinault Indian Nation's New Generations Building in Taholah, Washington. In March 2014, the Quinault Indian Reservation hired planners to work with the community to develop a plan for the relocation of the village. The master plan resulting from this effort directs the development of a new village beyond the tsunami zone and flooding inundation areas. The new village will replicate the uses in the lower village and will include single and multifamily residential, commercial, public, and institutional land uses. The plan also includes new streets and provides for open spaces, parks, and other recreational facilities. Photo credit: ©Larry Workman, Quinault Indian Nation.

Process Description

This chapter's authors have scientific knowledge and credibility in the topical areas covered. In particular, the authors span a variety of social science disciplines, allowing the team to analyze social systems from multiple disciplinary perspectives. Author selection for the chapter proceeded as follows.

First, the US Global Change Research Program (USGCRP) released a Request for Public Nominations. Interested scientists were either nominated or self-nominated and their names placed into a database. A concurrent Request for Public Nominations also solicited scientists to serve as chapter leads. Both lists were reviewed by the USGCRP, with input from the coordinating lead author (CLA) and from the National Climate Assessment (NCA) Federal Steering Committee. All chapter lead (CL) and agency chapter lead (ACL) authors were selected by the USGCRP. The CLA, CL, and ACLs then convened to review the author nominations list and identify potential chapter authors. The list was coded for diverse disciplinary expertise, and a subset was identified that met our requirements for analysis.

In the second phase, the CLA and CL used both the list of nominees and a list of other scientists who had relevant expertise to build an author team that was representative of diverse social science disciplines, institutional affiliations (federal agencies and academic and research institutions), depth of subject-matter expertise, and knowledge of proposed topics.

Lastly, the authors were contacted by the CL to determine their level of interest and willingness to serve as experts on the first Human Social Systems chapter in the NCA. One author, Dr. Kyle Whyte, was invited to lead a different chapter of the NCA after the process had begun. Because his disciplinary expertise was needed on this chapter, Dr. Whyte was asked to remain as an author on this chapter as well. Although this was unusual, all authors felt it was the best course of action given the team's ongoing conversations.

In January 2022, the author team held a public engagement workshop, where the public was invited to weigh in on the prospectus stage of our chapter. Public comments were therefore incorporated at multiple stages of chapter development.

To ensure Tribal sovereignty, the chapter lead, Elizabeth Marino, chapter author Melissa Watkinson-Schutten, and the NCA5 director, Allison Crimmins, discussed and consulted on the contents of Box 20.1 and accompanying photograph with the Tribal Council of Quinault Indian Nation. Formal permission was received through a vote to include this information in this NCA chapter.

Key Message 20.1

Social Systems Are Changing the Climate and Distributing Its Impacts Inequitably

Description of Evidence Base

Decades of rigorous social science research identifies numerous human-caused drivers of climate change, with the burning of fossil fuels and resulting greenhouse gas (GHG) emissions being of great importance.[11,255,256] Human-caused drivers encompass social systems and individual and aggregated human actions causing GHG emissions, as well as societal factors shaping and conditioning those actions, emphasizing institutional or large-scale processes of social structure. Most research on how social systems produce and distribute climate change focuses on anthropogenic drivers and involves longitudinal analyses of carbon emissions for the world's nations, while subnational analyses of emissions, including for US states and smaller units such as corporations and power plants, are becoming increasingly common (e.g., Galli-Robertson and Collins 2019;[257] Grant et al. 2020;[10] Jorgenson et al. 2019;[61] Pulver and Manski 2021[258]). To generate the body of knowledge summarized here, researchers merge aggregate data for societal factors (e.g., economic growth, population, inequality, etc.) with emissions data and use many statistical modeling techniques, such as multilevel regression analysis and longitudinal regression analysis, to examine changes over time and to test linear and nonlinear hypotheses regarding the relationships between social systems and emissions.[259]

Empirical research seeks to analyze these processes and interrelationships at different spatial scales and temporal resolutions. When the unit of analysis is the nation-state, analyses usually examine data for most of the world's nations or are grouped in categories like higher- and lower-income nations or as particular regional clusters. Economic development (e.g., industrialization, GDP growth, wealth) and population dynamics (e.g., population size, population growth) are the most widely analyzed anthropogenic drivers. Other societal factors with many dimensions are analyzed as well, such as urbanization, which may lead to different findings, depending on which dimension is being modeled (e.g., urban density, urban slum prevalence, percent of overall population residing in urban areas) and at which scale (e.g., cross-national, subnational).[61,255]

Analyses of governance are often found in public policy and political science research. These literatures recognize that governments are frequently in the position to support human well-being and survival through policy interventions but also demonstrate that these policy processes interact with the institutions and conventions of human social systems and can play a role in the perpetuation of structural inequalities.

It is well-documented that land-use policies, including historic practices such as redlining and other governmental decisions, have concentrated hazard risk into zones of vulnerability and largely determined who will inhabit those zones.[260,261,262] Some disaster risk-reduction strategies and policy decisions function as disaster risk creation, while disaster relief has been shown to incentivize poor land-use decisions by local government.[263,264,265] An extensive literature exists in fields such as public administration, social geography, and political science, providing an evidence base that is generally in agreement regarding the role that governance and institutional arrangements play.

Major Uncertainties and Research Gaps

Although addressing human drivers is necessary for reducing GHG emissions, how to effectively harness global drivers of change is uncertain, given institutional inertia and the complexity of cross-scale social change. Curbing economic growth is not expected to proceed evenly at a global scale, given unbalanced resources, policies, and institutional mechanisms to promote change. The scale at which mitigation of

human drivers can be most effective is unclear, as efforts need to be multi-scalar and operate across various social-structural and spatial contexts.

There is uncertainty as to whether bureaucratic discretion can be utilized in service of adaptive governance, as opposed to when legal and regulatory changes are needed. Scholars are investigating the bounds of law and policy that limit and create options for climate adaptation, risk reduction, and support for communities faced with structural racism and discrimination. Transformative adaptive governance is only possible if there is action at all levels of government and civil society.[266] This action is dependent on key governance choices, including what problems to focus resources on, at what level of government actions should be taken, the timing of such actions, the mode of governance to be utilized, and what norms to rely on.[267] More research would be needed in order to identify the limitations of discretion and how best to build adaptive governance mechanisms.

Another important gap is a lack of alternatives to cost–benefit mechanisms, such as models that can account for the value of preserving community, protecting lifeways, and accounting for historic disenfranchisement that drives down economic value.

Description of Confidence and Likelihood

There is an extensive body of empirical research in the social sciences on the societal drivers of climate change.[61,255,268] Therefore, there is *very high confidence* that social systems create climate change via GHG emissions and that these emissions are mitigated by societal characteristics. Empirical research and theoretical modeling of human activity show that human systems demonstrably impact the atmospheric conditions of the Earth. A diverse set of studies also show that world economic integration, ongoing economic growth, population growth, and high levels of inequality are correlated with GHG emissions and continue to trend upward. A large body of research demonstrates correlations in world economic integration, life expectancy, and income distribution with GHG emissions. This body of literature is unambiguous. Therefore, the authors have *very high confidence* that social systems also inequitably distribute the benefits of energy consumption and the impacts of GHG emissions.

Case study literature and disaster studies for at least 40 years have shown that disasters do not affect everyone equitably; therefore, authors also have *high confidence* that the impacts of climate will be distributed inequitably. Public administration research, as well as case study literature from geography and anthropology, corroborates this claim.

The interactions between a variety of governance processes and hazards and disasters are well studied. Land-use policies, and in particular their impacts, have been studied in depth and show disparate impacts over time.[265,269] Institutional decisions, policies, and bureaucratic discretion have also been shown to cause greater harm to some populations than to others.[270,271] Here the authors do not suggest that inequitable distribution of climate impacts is certain in the future, but there is a robust literature that suggests governance decisions are clearly linked to how risk emerges within human and social life, thus leading to an assessment of *very high confidence*. There is research that demonstrates adaptive measures to climate changes, such as hazard mitigation, are similarly structured by governance decisions; but because there is a much shorter time frame for studying climate change–specific adaptation, authors have assigned *medium confidence*.

Key Message 20.2

Social Systems Structure How People Know and Communicate About Climate Change

Description of Evidence Base

There is a rapidly increasing, diverse, and transdisciplinary evidence base supporting the conclusion that social systems structure how people understand, think about, and respond to climate change in fundamental ways. Work on this topic comes out of philosophy, science and technological studies, intellectual history, Indigenous studies, psychology, sociology, and anthropology, among other fields, and includes a wide diversity of theoretical and methodological approaches to evidence gathering (including epistemological studies, survey research, ethnography, and others).

The evidence base includes studies that demarcate the diverse ways in which human–nature interactions are conceived, including worldviews that integrate human and nonhuman society. The evidence base also includes research that demonstrates that insights Indigenous Peoples and others make about climate drivers and action reflect their social position, history, culture, and connectedness to the environment.[77,105,119,122,123,125,128,163,272,273,274]

A robust literature in social psychology and science communication, among other fields, demonstrates how people respond to different messages and information about climate change and why different types of climate change engagement efforts have differential outcomes. These fields offer insight into how effective communication and engagement can promote decision-making and action through multiple pathways, including provision of actionable knowledge, growth of motivation to act, and development of new skills and sense of efficacy. However, while there is often much hope around initiatives to change household behaviors through communications and engagement, the impacts of these initiatives are oftentimes relatively small, if generally robust.[172,173]

Major Uncertainties and Research Gaps

The literature is clear that knowledge is influenced by social position, culture, and history, and that knowledge and justice are related; it is also clear that people engage with climate change in diverse ways as a function of who they are and how efforts to communicate climate change are designed and delivered. There are significant gaps in the relevant research base, however. One is that studies are only beginning to emerge that show how people who experience injustice related to climate change envision different solutions to climate change. While the available evidence is strong in some domains, such as fire management,[109,110] it is not comprehensive in other domains, such as with respect to responses among diverse BIPOC (Black, Indigenous, and People of Color) communities and communities with lower incomes that are experiencing a range of impacts and challenges. In addition, in part because it is so broad and comes from many different fields of study, the evidence base regarding social systems and how people understand and engage with climate change lacks integration across fields (and even within subfields). Although there are growing efforts to use coproduction approaches, as well as meta-analytic and other synthesizing approaches, to study social systems, there is a clear need for additional synergistic and interdisciplinary research that explores these issues from a diverse set of perspectives and using diverse methodological tools. Additionally, there is a need for more studies that employ coproduction approaches to understand more about how diverse knowledge contributes to climate adaptation and mitigation among communities that have been shaped by prior unjust experiences.[138,139,140]

While guidance to improve communications and engagement efforts has grown and strengthened in the past decades, there are also areas of uncertainty and research gaps in this domain. One such area concerns

the role of emotion in engagement and communication. Researchers and practitioners debate whether messages that evoke fear, guilt, hope, or other emotions can motivate behavior change effectively.[275] Climate communication that appeals to different emotions as a means to engage audiences and spur action is a growing research area, but there are conflicting findings about its effectiveness. Another research gap due to a lack of qualitative and quantitative studies involves the communication needs of vulnerable populations.[148] More generally, extant evidence tends to come from correlational studies and relatively small-scale and/or lab-based experiments with nonrepresentative samples, and there are open questions in the literature regarding the robustness, generalizability, and applicability of the research base to real-world engagement and communication efforts.

Description of Confidence and Likelihood

There is extensive evidence in both case study and other research that people's context impacts their understanding of knowledge and, in turn, how they experience climate change. Therefore, we have *high confidence* that people's histories, educations, cultures, and ethics determine how they understand climate change. Given the cultural diversity of knowledge and knowledge communication found in anthropology and other fields, we have *high confidence* that these knowledges take different forms.

Although there is evidence from within and beyond the climate change domain to suggest that clear objectives and benchmarks promote desired outcomes regarding public engagement efforts, there are gaps with regard to the diversity of communities that have been formally studied. For example, much attention has been dedicated to communicating more effectively across ideological divides. On the other hand, the authors identify research gaps regarding knowledge of the communication needs of overburdened communities that are potentially most vulnerable to climate change impacts. Therefore, the authors have *medium confidence* that building such components into engagement efforts will actually promote desired outcomes across diverse communities.

There is extensive evidence across multiple fields of study and practice that converges on a consistent finding: namely, that climate change is a challenging issue on which to engage diverse publics. This is due in part to the complex nature of the issue, as well as to pervasive deep uncertainty, such as tipping points, within the climate system and how social systems (including political systems and governance) will continue to adapt to evolving risks. Therefore, the author team has *high confidence* that these and other factors pose significant challenges to effective engagement.

Although there is a growing recognition of the importance of community-driven engagement and inclusion of diverse forms of knowledge in collective decision-making in the climate change space, relatively less attention has been paid in the literature to promoting (climate) justice through inclusion of diverse perspectives and epistemologies. Therefore, the existing evidence base provides for *medium confidence* that greater inclusion of diverse community perspectives and types of knowing in engagement and decision-making efforts can provide an effective mechanism to promote justice.

Key Message 20.3

Climate Justice Is Possible If Processes Like Migration and Energy Transitions Are Equitable

Description of Evidence Base

Research on environmental migration and relocation is represented in multiple social science disciplines, including demography, sociology, geography, anthropology, regional and urban planning, and urban studies. Research methods vary widely, from ethnography and other qualitative approaches to statistical analysis of survey, census, and administrative records and to scenario-based modeling. Much of the empirical research focuses on migration in response to extreme disaster events in order to speculate on future climate–migration interactions. Therefore, event-based case study approaches dominate the literature.[276,277] Meta-analyses of the climate migration literature have shown that hazards have heterogeneous effects on human migration, sometimes driving people out of and sometimes attracting people to hazard-affected areas and sometimes not having any effect.[278,279,280,281,282] In the United States, a few surveys ask respondents why they moved, although only very small percentages (less than 1%) name disasters or the environment as their reason for moving,[180,181] supporting the statement that the environment is not a major driver of internal US migration. Research on governance of housing recovery after disasters is based on a growing body of evidence about disaster impacts on housing, post-disaster permanent housing recovery, home buyout programs, and social and spatial inequalities therein, which originated in disaster research centers and has expanded to include scholars in all of the aforementioned disciplines.

This Key Message and supporting text were based on the extensive environmental justice, climate justice, and just transition literature. The overburdening and overexposure of low-income and BIPOC communities to environmental injustices and negative climate change impacts, as well as their lack of access to environmental amenities and green spaces, has been well documented, particularly by scholars such as Robert Bullard (e.g. Bullard 1994,[1] 1996,[241] 2001,[242] 2008[74]).

While the majority of environmental justice literature focuses on the distributional arm of justice, some key literature has discussed and demonstrated the importance of recognitional and procedural justice ameliorating histories of environmental injustices (e.g., Corburn 2003;[283] Rigolon and Németh 2018;[284] Whyte 2011[3]). The literature on just transition largely focuses on the transition to a low-carbon economy via the increased use of green energy.[238] Much of that literature is based on European case studies. As such, there are not many US case studies to discuss, and even fewer successful ones. However, the literature on green infrastructure, which can be considered a part of just transition strategies, is better developed, although it is still evolving (e.g., Zuniga-Teran et al. 2021[246]). Nevertheless, the literature available on these topics, albeit limited in some areas, is corroborating, clear, consistent, and overwhelmingly in agreement regarding the history of environmental racism, the evidence of disparate exposure and impact, and the potential for perpetuation in the context of climate.

Major Uncertainties and Research Gaps

There are several research gaps within this research areas. One such area is research on nontraditional hazardous scenarios or built-environment challenges, including the distribution and condition of critical infrastructure systems and utility services that pose risks in the instance of failure.[247] One well-known example of this is the Flint, Michigan, water crisis and the disrepair of drinking water systems that resulted in corrosion and lead poisoning in a majority-Black community. Emerging literatures are filling this gap in terms of justice in the areas of energy, sewerage, stormwater, transport infrastructure, and beyond. Similarly, research in just transitions is still developing, especially with regard to green energy and jobs, two

of the major focuses of the literature, and has few resolved or successful case studies. This is mainly because this phenomenon is relatively recent and the outcomes related to efforts are still to be determined.

Observational studies of environmental drivers of migration cannot predict the quantity or types of migration that will occur in the future, especially as changes occur in the environment, the economy, governance, risk perception, and systems exacerbating or mitigating social inequalities. Scenarios of expected conditions may allow for broad generalizations;[285] however, predicting the timing, location, and magnitude of climate-related hazards that may provoke migration requires many assumptions and uncertainties (e.g., Rigaud et al. 2018;[286] Clement et al. 2021[287]). Social science may contribute to filling a gap regarding how social systems influence collective and individual decisions to relocate away from or adapt in place to climate change impacts. There are growing literatures on immobility, whether climate induced[288] or voluntary.[289] Additional research gaps enumerated in a recent review include investigations of the long-term outcomes of disaster evacuees and the effects of climate change on demographic subgroups, such as children or older adults, and small populations, such as Indigenous People.[290]

There are not enough data available to evaluate the new federal initiatives mentioned in this section. In the past it has been challenging to understand environmental justice implications in federal policies because of a lack of data. FEMA, for example, has not historically collected data on race or ethnicity as part of its assistance programs. Recent changes have permitted this data to be collected,[291] and we anticipate new insights in the coming years.

Description of Confidence and Likelihood

Historical corollaries and new policies on environmental justice provide an opportunity for communities to envision climate justice; however, current case study research and ongoing research on environmental justice outcomes show that such a transition will be difficult and that there remain deep inequities in accessing environmental benefits and suffering environmental burdens. Additionally, it is unclear whether governance structures can adapt quickly enough to respond to climate risks and other societal pressures. There is therefore *medium confidence* that climate justice is possible. An extensive literature in demography, anthropology, geography, public administration, and legal studies demonstrates that migration is a complex phenomenon that has multiple push and pull factors and is mitigated by socioeconomic conditions. This research base gives us *medium confidence* that migration will impact the three categories of environmental justice or exacerbate these injustices. There is extensive literature that suggests justice is a complex, multifaceted process that includes understanding how benefits, burdens, and decision-making around climate change are distributed among diverse groups;[1] therefore, we have *high confidence* that adaptation to a changing climate and changes to energy production require a whole-systems approach that must consider the social dynamics of race, ethnicity, rurality, poverty, and infrastructure equity, among other factors.

Introduction

The Northeast landscape varies from the rural New England coast to the urbanized corridor from Boston to the Mid-Atlantic and inland to the heavily forested Appalachian Mountains. New York, Pennsylvania, Maryland, Delaware, West Virginia, and the District of Columbia all contain parts of the Chesapeake Bay Estuary, the largest estuary in the United States. The Northeast is the homeland of Indigenous Peoples, including 18 Federally Recognized Tribal Nations and many Indigenous Peoples both within the region and who were removed from their lands in the Northeast and relocated to other regions of the United States. Much of the region's employment is in the professional sectors, but jobs related to the natural environment and tourism remain culturally and economically important.[1] Heritage industries tied to resources and agriculture still shape New England and the Mid-Atlantic, including fishing at the coasts, farming in rural areas of Pennsylvania and Maryland, forestry in northern New England, and mining in West Virginia. Seasonal tourism tied to outdoor recreation is particularly important, with summer tourism in coastal communities, fall tourism driven by changing leaves, and winter tourism based on cold-weather sports. Tourism is also important in the cities year-round, with visitors attracted to historical sites, the arts, and the diverse cultures of large cities such as Boston, New York City, Philadelphia, Baltimore, and Washington, DC.

The population of the Northeast has increased by approximately 4.4% since 2010, totaling more than 67 million people. The Mid-Atlantic states experienced the largest increases, with the District of Columbia increasing by 14.6% and Delaware by 10.2%. Some states with larger rural areas—Maine, Pennsylvania, Vermont, and Connecticut—experienced more modest population growth or remained stable. West Virginia was the only state to lose population, declining by 3.2%.[2,3]

Much of the information about the impacts of climate change on the region presented in the Fourth National Climate Assessment (NCA4) remains true today.[4] Urban residents still face increased exposure to extreme heat events, flooding, and episodes of poor air quality. Likewise, rural areas are still susceptible to droughts and floods that affect agricultural productivity and ecosystem function. These events still pose compounding threats to aging transportation, water, and wastewater infrastructure. The communities most vulnerable to climate risks remain those that are historically overburdened and economically disadvantaged in both rural and urban areas. As extreme events continue to occur frequently, these changes are becoming stressors throughout the region—in rural interiors, urban corridors, and the ecosystems supporting coastal communities.

Many early adopters of both mitigation and adaptation action have been in the Northeast. Hurricane Sandy (2012) drove some of this action through programs like the Rebuild by Design effort, which focused on making projects related to disaster rebuilding more resilient to all hazards.[5] In 2014, thirteen projects that won the National Disaster Resilience Competition were located in the Northeast, and by 2022 these projects were in design and construction phases, with some projects substantially complete.[6,7] Northeast cities and states participated in numerous other efforts, from the Rockefeller Foundation's 100 Resilient Cities program to Massachusetts's landmark integration of climate adaptation into its FEMA State Hazard Mitigation Plan.[8] States, Tribal Nations, and local governments are also beginning to fund both planning and project implementation with non-grant public funding, and private-sector actors are increasingly self-funding their own action. Advancements in adaptation and mitigation efforts in the Northeast provide an opportunity to document progress and identify remaining knowledge gaps that constrain or enable climate action.

In the Northeast, both adaptation and mitigation actions are proceeding, particularly in response to repeated impacts from extreme weather events (KM 21.1). Adaptation is also being documented in the ocean and coastal regions (KM 21.2). Human and ecosystem climate change impacts are disproportionately affecting overburdened communities and people, leading to an increased focus on equity in adaptation and mitigation efforts (KM 21.3). Deliberate action plans for both mitigation and adaptation are being completed throughout the Northeast by states, municipalities, and Tribal Nations (KM 21.4), but the progress of action in both the public and private sector will depend on the ability to fund and finance it (KM 21.5).

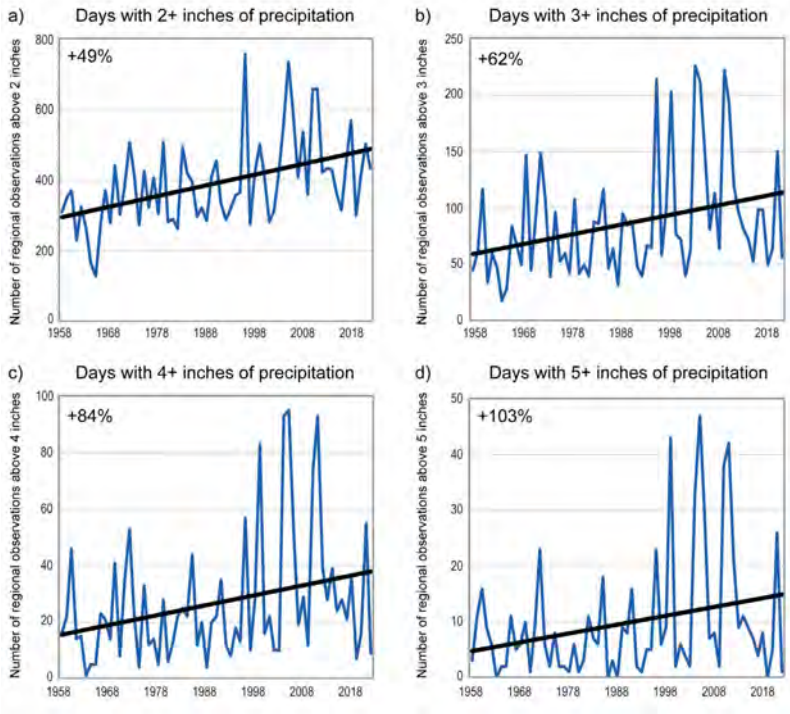
Key Message 21.1

Chronic Impacts of Extreme Weather Are Shaping Adaptation and Mitigation Efforts

The Northeast continues to be confronted with extreme weather, most notably extreme precipitation—which has caused problematic flooding across the region—and heatwaves (*very likely*, *high confidence*). In response, climate adaptation and mitigation efforts, including nature-based solutions, have increased across the region (*high confidence*), with a focus on emissions reductions, carbon sequestration, and resilience building (*medium confidence*).

Precipitation in the Northeast has increased in all seasons (Figure 2.4),[292] and extreme precipitation events (defined as events with the top 1% of daily precipitation accumulations) have increased by about 60% in the region—the largest increase in the US (Figure 2.8; see also Figure 21.1). These changes may be due to an increase in tropical systems during the Atlantic hurricane season in September and October, especially at interior locations as far inland as West Virginia.[9,10,11,12] The increase in extreme precipitation and associated flooding could also be due to the higher overall water availability throughout the region.[13]

Trends in Extreme Precipitation in the Northeast

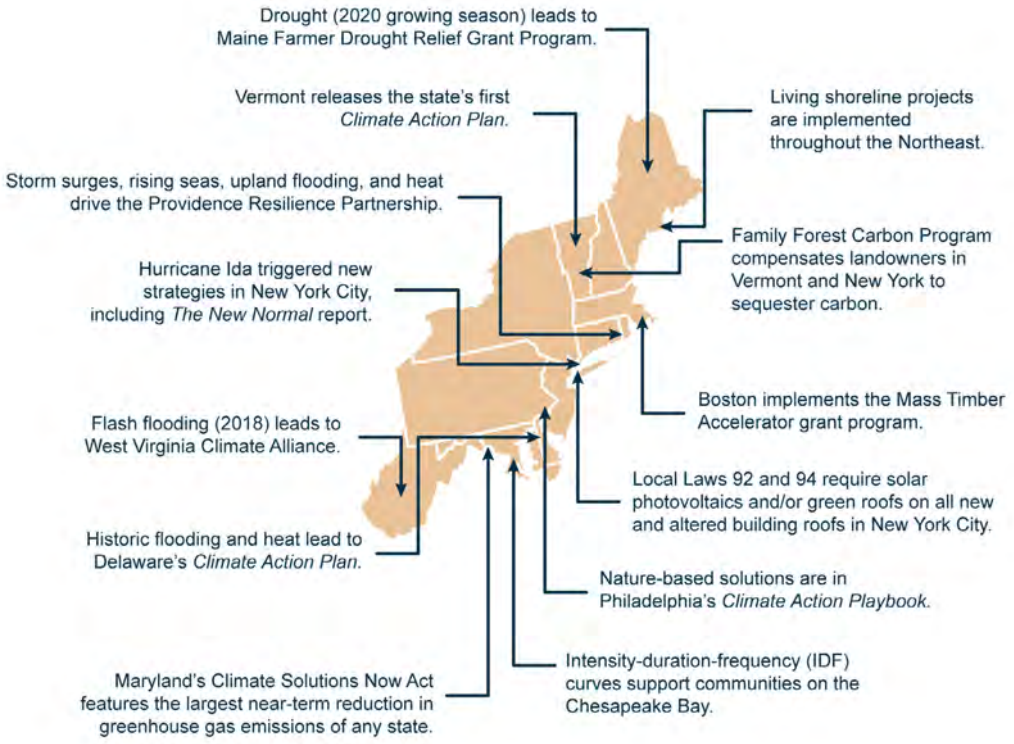


The number of days in the Northeast with extreme precipitation has increased.

Figure 21.1. The four charts show the number of daily events per year with precipitation totals equal to or exceeding 2, 3, 4, and 5 inches from 1958–2022 (blue lines), along with trend lines (black) computed from linear regressions over the full period. Numbers in the top left corner show the percent increase relative to the long-term average, computed as the difference between the end points of the trend lines divided by the 1958–2022 average. The number of daily events is defined as the total number of extreme precipitation accumulations recorded at all stations across the observing network in the Northeast. See the figure metadata for details on the methodology. The trends shown suggest an increase in the frequency of extreme precipitation, with larger increases for the more extreme precipitation events. Figure credit: USDA Forest Service, Drexel University, NOAA NCEI, and CISESS NC.

Urban and flash flooding is typically triggered by short-duration (e.g., sub-daily, sub-hourly), high-intensity, localized "cloudburst" events, often caused by convective thunderstorms. Although historical and forecasted trends in sub-daily precipitation event attributes and frequencies have not yet been evaluated for the region, the occurrence of these events has already begun to motivate action (Figure 21.2). For example, in 2021 after back-to-back storms (Hurricane Henri followed by Hurricane Ida) shattered records for the greatest one-hour rainfall events and resulted in 13 deaths, the City of New York committed to educate, train, and acclimate residents to the potential impacts of extreme weather, expand flood protection to include both inland and coastal communities, and reimagine its drainage system, among other initiatives.[14]

Examples of State and Local Responses to Extreme Weather



Northeastern states and cities have adopted a range of plans, programs, and policies in response to extreme weather, many of which include nature-based strategies.

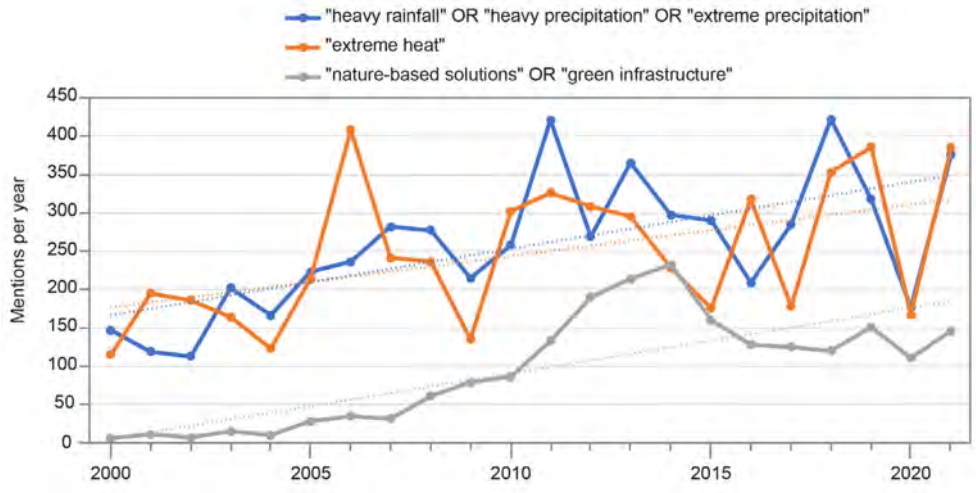
Figure 21.2. This map highlights efforts, many of which are nature-based, that address climate change impacts by building resilience or promoting mitigation measures. In some cases, these efforts are specific programs or projects, such as the Family Forest Carbon Program in Vermont and New York. In other cases, local and statewide plans include broader attention on natural and nature-based strategies. Figure credit: Drexel University and USDA Forest Service.

The frequency of droughts in the Northeast decreased between 1901 and 2015, albeit not as much as would have been expected given the region's increase in average precipitation.[15] Although higher overall humidity can reduce the effect of rising temperatures on how quickly water evaporates from crops,[16] farmers[17,18] and other stakeholders report impacts triggered by highly variable soil moisture. For example, thaw events, extended spring conditions, and longer mud seasons have reduced mobility on unpaved roads that are important for rural travel and logging operations.[19]

As in the rest of the country, the region's heatwaves are lasting longer and are more severe, generally increasing heat stress, especially in densely populated areas (KM 2.3). By midcentury, heat index values over 100°F are projected to increase threefold in the Northeast under an intermediate scenario (RCP4.5).[20]

Extreme weather creates a range of social, economic, and ecological impacts in urban, coastal, rural agricultural, and wild landscapes, as demonstrated by an increase in reporting on extreme weather in the Northeast media (Figure 21.3). Social vulnerability to climate stressors is unequally distributed throughout the region. Individuals who are low income, minority, and/or without high school diplomas are, respectively, 35%, 20%, and 20% more likely than individuals who are not members of those groups to live in areas with the highest projected traffic delays due to high tide flooding. Minorities in the region are 16% more likely than non-minorities to experience property damage or loss due to the highest projected inland flooding damages.[21] In New York City, high levels of social vulnerability to climate change are consistently found in neighborhoods with lower incomes and higher shares of African American and Hispanic residents.[22] Ecosystems are also becoming more vulnerable to extreme weather events as climate change increases stressors such as pests that survive in warmer winter nights.[23]

Northeast US Newspaper Mentions of Extreme Weather and Nature-Based Solutions



Mentions of extreme weather events and nature-based solutions are increasing across Northeast media.

Figure 21.3. As the Northeast continues to experience extreme weather events, news articles highlight the trend in climate action planning. Natural and nature-based features are a common strategy used in these efforts. Solid lines show mentions related to heavy precipitation (blue), extreme heat (orange), and nature-based solutions and green infrastructure (gray) during 2000–2021, with dotted lines showing the estimated trend line for each category. Figure credit: Drexel University and USDA Forest Service.

Future increases in heatwaves are projected to increase mortality rates in the region's major urban areas (KM 15.1).[24] Among workers who are exposed to weather conditions, minorities are 7% more likely than non-minorities to lose labor hours under 2°C (3.6°F) of global warming.[21] Extreme heat is also putting increased pressure on emergency managers and utility corporations, as well as causing human mortality.[25]

High population density, problematic land-use configurations, industry and other pollution sources, contaminated soils, aging infrastructure, and a legacy of buried and/or heavily modified natural drainage systems exacerbate extreme weather impacts in urban areas (KM 12.2).[26] Even under non-extreme weather conditions, impervious surfaces (e.g., sidewalks, roofs, roadways, compacted lawns) generate large quantities of runoff from precipitation, yielding nonpoint source pollution, streambank erosion, habitat degradation,

downstream flooding, impaired mobility, and reduced access to services. Extreme weather accelerates and amplifies these phenomena. Localized rainfall flooding can damage homes and businesses with below- or at-grade spaces (e.g., basements, ground floors, subways). Hurricane Ida triggered rainfall flooding that killed 11 people in New York City who could not escape below-grade dwellings[27] and inundated below-grade sections of Philadelphia's Vine Street Expressway. In Baltimore, flooding interrupts basic services, including access to food distribution centers, schools, childcare facilities, health services (e.g., dialysis or methadone clinics); in addition, the city's elderly, poor, mentally ill, mobility-constrained, and those with limited experience of flooding were identified as the most susceptible to flooding effects.[28] More broadly across Maryland, probabilistic flood mapping and recent flood events indicate that flood risks extend beyond the 100-year floodplain in some places, particularly in urban watersheds.[29]

Increased precipitation can also impact less intensively developed areas and along the coasts. Observed and projected increases in precipitation in the Susquehanna River basin, which contributes about half of all freshwater discharges into the Chesapeake Bay, are drivers for flood risk, poor water quality, and changes to habitats in the bay.[30,31] Wetter springs are expected to continue to delay planting, postpone harvests, and reduce crop yields.[23]

Stronger storm surges during tropical systems and nor'easters increase the risk of coastal flooding, also exacerbated by sea level rise.[32,33] Flood hazards for coastal cities are projected to increase in frequency and magnitude in the coming decades in the absence of near-term adaptive measures.[34] In August 2020, Tropical Storm Isaias flooded the Eastwick neighborhood of southwest Philadelphia. This overburdened community is home to one of the largest Superfund sites in the country and also faces coastal and compound flood risks due to sea level rise from the Delaware River.

Governmental and nongovernmental groups are mapping hazards to assist in responding to extreme events. New York City and Boston developed detailed maps of the portions of each city that are at risk of rainfall-induced inland flooding under coincident tidal conditions and sea level rise. Maps of croplands and forests most vulnerable to saltwater intrusion are also being developed.[35] Heat vulnerability maps have been developed for cities (e.g., Philadelphia), counties (e.g., Essex County, New York), and states (e.g., Vermont) throughout the region. Such maps can assist with identifying at-risk communities. Heat risk-reduction strategies tend to emphasize direct assistance to at-risk residents and impacts on energy utilities. Chelsea, Massachusetts, and New York City have distributed air conditioners to reduce the impacts of extreme heat, and Philadelphia recently released a Beat the Heat Toolkit.

States, regional planning commissions, Tribal Nations, and localities are also responding by incorporating climate resilience into FEMA hazard mitigation plans (HMPs; KM 31.4). Many action plans are developed through collaborative public–private processes. Atlantic County, New Jersey, has initiated a Regional Resilience and Adaptation Action Plan through a partnership between the New Jersey Bureau of Climate Resilience Planning and various regional stakeholder groups. The Stafford Act[36] requires that states and Tribes submit approved HMPs to FEMA every five years to be eligible for nonemergency Stafford Act disaster assistance and FEMA hazard mitigation grants. The act also requires each state to establish a process to support development of local HMPs. Climate-resilient HMPs incorporate downscaled climate projections, resident experiences, and local visions. Increasingly, HMPs directly address the goals of other plans developed at the local, regional, Tribal, or state level, including sustainability plans and comprehensive plans (e.g., Nashua, New Hampshire; Springfield and Boston, Massachusetts; Shinnecock Nation; and New York City). In most cases, these efforts are in the planning phase, but some early-adopter locations are beginning to implement their resilience projects. Local and state FEMA hazard mitigation planning guides now encourage climate-informed planning and projects that incorporate resilience.[37,38]

With increased awareness of extreme weather impacts, climate action plans and projects in the Northeast are utilizing natural and nature-based features (NNBFs) more frequently (Figure 21.2). NNBFs restore landscape resilience to disturbances, protect downstream water bodies, and deliver a range of co-benefits that protect public health, reduce flood damage, improve water and air quality, and control ambient air temperatures (KM 9.3). NNBFs utilize plant or soil systems for environmental, economic, and social benefits.[39] Several recent studies focused in New Jersey, New York, and Connecticut emphasize the role of NNBFs in buffering coastal flood losses,[40,41] detaining and retaining runoff,[42,43] reducing combined sewer overflows,[44] alleviating heat impacts,[45,46] and introducing vegetation that is resilient to future floods and droughts.[47] Changes in precipitation can also reduce the stormwater capture performance of NNBFs,[42,48,49] and the adaptation value of NNBFs can depend heavily on unique local conditions.[50] Several Tribal NNBFs are also in place across the Northeast (KM 16.3). For example, the Shinnecock Nation has developed a kelp aquaculture farm and a living shoreline featuring oyster reefs on Long Island, New York.[51] In partnership with the Town of Mashpee, Massachusetts, the Mashpee Wampanoag Tribe also built an oyster reef.[52] The Wampanoag Tribe of Gay Head (Aquinnah), Massachusetts, rebuilt and replanted beach dunes for coastal protection.[53]

Climate mitigation is also a target for NNBFs, including carbon sequestration and greenhouse gas (GHG) emissions reductions.[54,55,56] Local, Tribal, and state planners are moving toward multi-objective approaches when incorporating NNBFs as part of the toolbox for climate adaptation and mitigation, with increasing focus on equitable climate outcomes where co-benefits are needed for heat, flooding, and well-being (Figure 21.2).

Key Message 21.2

Ocean and Coastal Impacts Are Driving Adaptation to Climate Change

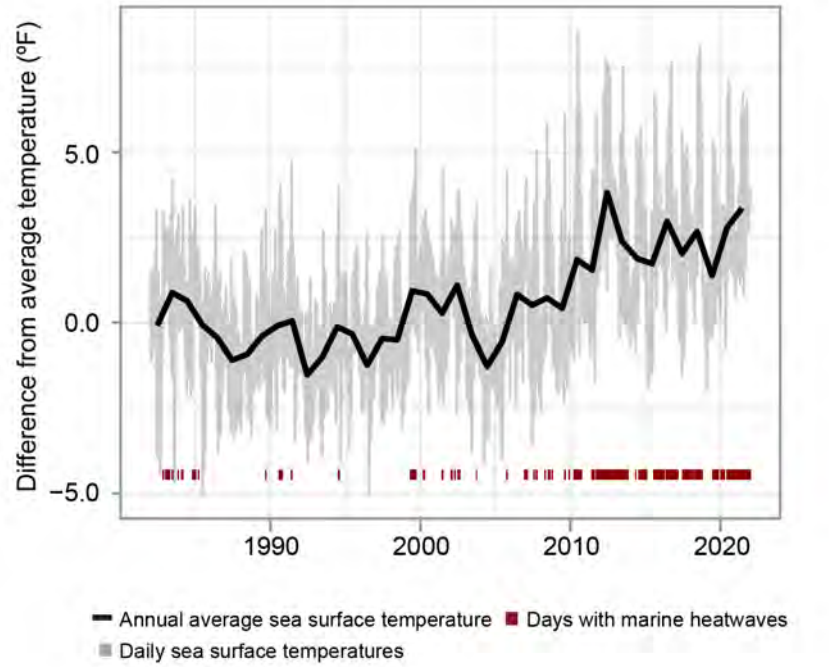
The ocean and coastal habitats in the Northeast are experiencing changes that are unprecedented in recorded history, including ocean warming, marine heatwaves, sea level rise, and ocean acidification (*high confidence*). Changing ocean conditions are causing significant shifts in the distribution, productivity, and seasonal timing of life-cycle events of living marine resources in the Northeast (*high confidence*). These impacts have spurred adaptation efforts such as coastal wetland restoration and changes in fishing behavior (*high confidence*).

Ocean warming, more frequent and intense marine heatwaves, sea level rise, and ocean acidification are harming aquatic ecosystems and ecosystem services, and these impacts are expected to be exacerbated by future climate change (KMs 2.1, 3.4, 9.1, 9.2, 10.1; App. 4.4).[57,58,59,60] Climate-driven shifts in distribution, productivity, and phenology (seasonal timing of life-cycle events) are increasing in prevalence and magnitude across species, from phytoplankton to whales.[59,61]

Ocean temperatures in the continental shelf bottom waters of the Northeast have increased by as much as 0.15°F to 0.7°F per decade (Friedland et al. 2020) due to changes in atmospheric circulation from a persisting positive North Atlantic Oscillation (NAO; a large-scale climatic phenomenon) and a weaker Atlantic Meridional Overturning Circulation.[62] The northward shift of the Gulf Stream increased the salinity and temperature of subsurface waters on the Northwest Atlantic shelf.[63] Several notable marine heatwaves affected the Northwest Atlantic over the last decade (Figure 21.4),[63,64,65] associated with Gulf Stream variability, atmospheric jet stream motions, and the increased presence of masses of warm water formed from the Gulf Stream called warm core rings.[66] Changes in ocean temperature and circulation have also decreased the extent, temperature, and duration of the cold pool, a near-bottom coldwater feature in the Mid-Atlantic and an important habitat for fish productivity.[58,67]

These changes are impacting productivity at the base of the region's ocean ecosystem and changing the composition of the phytoplankton community.[68] The overall diversity and abundance of the zooplankton community has increased,[68] but the biomass of key zooplankton species has declined.[59,69] These changes can restructure communities and have cascading effects throughout the food web. For example, the negative impact of warming on the copepod *Calanus* has been linked to shifts in the distribution of right whales along the Northeast shelf.[70,71]

Ocean Temperatures and Marine Heatwaves

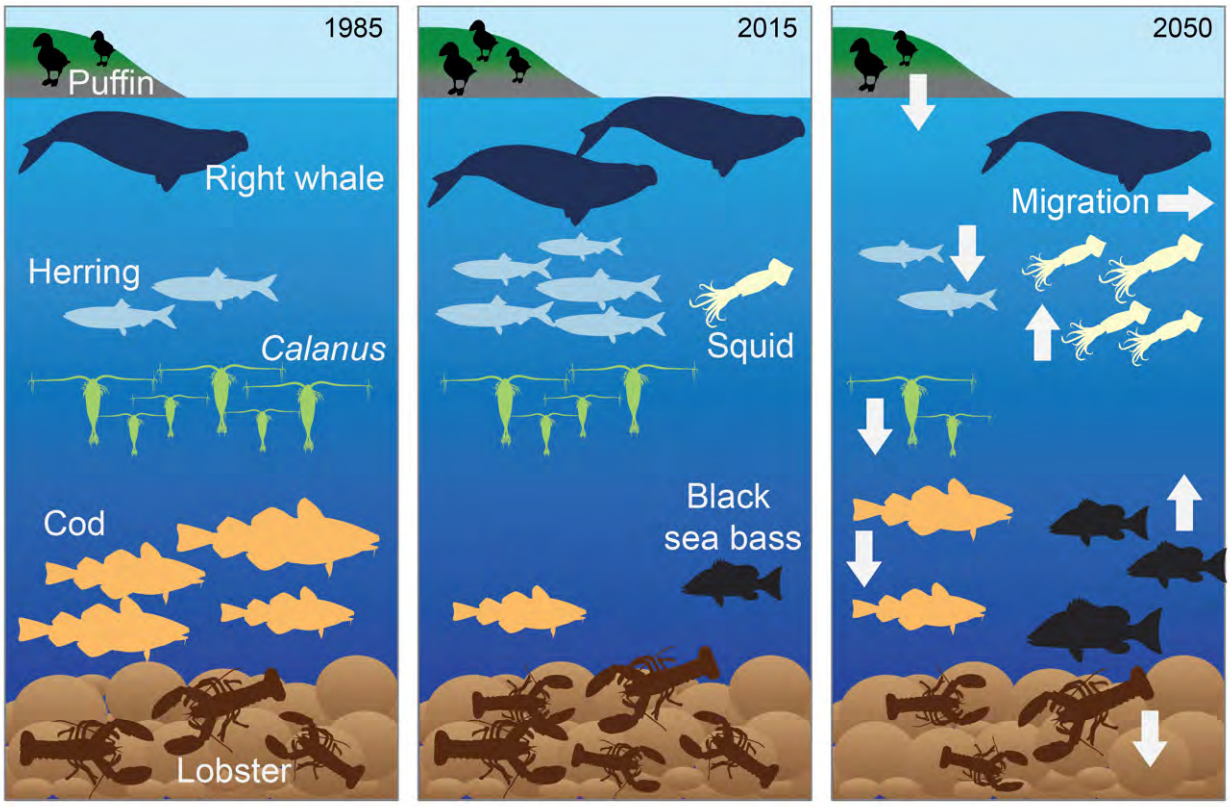


Oceans are growing warmer and marine heatwaves are more frequent, which is impacting marine ecosystems in the Northeast.

Figure 21.4. Annual average sea surface temperature (SST) anomalies (solid black line) and daily SST anomalies (light gray line) for the Gulf of Maine (region defined as ecological production unit, an ecologically distinct ecosystem). Differences from the long-term average are estimated using a 30-year climatology reference period of 1982–2011. Days meeting marine heatwave criteria are noted (red tick marks). Marine heatwave status was determined following the methods of Hobday et al. (2016).[72] The figure shows continued warming of the Gulf of Maine, with 2022 among the warmest years on record. In addition to the warming trend, the periodicity of extreme temperature events (i.e., marine heatwaves) has increased in the region. Adapted from Gulf of Maine Research Institute 2022.[73]

Fish stocks are shifting northeastward along the shelf and into deeper waters.[58] Traditional Mid-Atlantic fish species (e.g., black sea bass)[74,75] are increasing, and subarctic species (e.g., northern shrimp and Atlantic cod)[59] face declines in the Gulf of Maine (Figure 21.5). Warming is changing the distribution of bottom-dwelling species, including American lobster, Atlantic surf clams, and sea scallops (Figure 21.6).[76,77] New research directions focus on the impacts these changes have on early life stages for key species like Atlantic mackerel.[78]

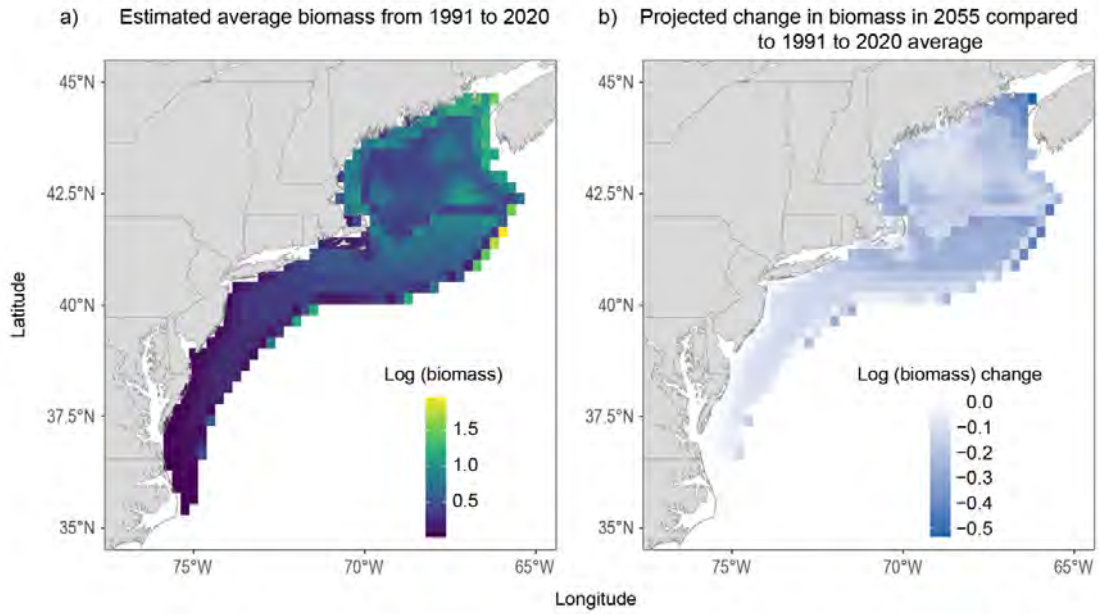
Past (1985), Present (2015), and Future (2050) of the Gulf of Maine Ecosystem



Shifts in the abundance and composition of species in the Gulf of Maine are expected to continue with additional warming.

Figure 21.5. In 1985, conditions in the Gulf of Maine ecosystem were cool, and subpolar species (puffin, right whales, and Atlantic herring) were not abundant due to human activities and natural variability. By 2015, Atlantic cod abundance was low due to overfishing and rising temperatures, whereas temperate species (e.g., black sea bass and squid) became prevalent due to warming. Under an intermediate scenario (RCP4.5), by 2050 many subpolar species (e.g., lobster, Atlantic cod, Atlantic herring, and *Calanus*, a copepod) are expected to decline (down arrows), and temperate species will increase (upward arrows). With better management, Atlantic cod abundance will tend to increase, but it will be counteracted by decreased productivity due to warming. Right whales will increase with better management but are expected to move out of the Gulf of Maine (horizontal arrow) due to the impacts of warming on the distribution and abundance of their prey. Local fishing communities will need to shift effort to harvest species that have become more abundant. Adapted from Pershing et al. 2021[59] [CC BY 4.0].

Changing Distribution of Fishery Resources in the Northwest Atlantic Ocean



The distribution and abundance of American lobster are expected to decrease by midcentury.

Figure 21.6. The figure shows (**a**) predicted changes in American lobster (*Homarus americanus*) distribution and abundance based on the estimated baseline biomass (log-transformed scale) from 1991 to 2020 (the color scale ranges from yellow [high biomass] to purple [low biomass]) and (**b**) future projected change in biomass in 2055 compared to the baseline period (the color scale ranges from no change [white] to a decrease in biomass [darker blue]). Projections suggest a decrease in the future biomass of lobster due to ocean warming. Adapted from Allyn et al. 2020[79] [CC0 1.0].

The timing of important life-history events, such as fish feeding and spawning migrations, is shifting in the Northeast. Spring and autumn phytoplankton blooms occurred later in recent decades.[80] Larval fish occurrence and fish migration are both happening earlier.[81,82,83] Warmwater fish remain longer in Rhode Island's Narragansett Bay, while coldwater species stay for shorter periods,[84] changing when species can be fished. Warming seas are linked to increased cold-stunning events for Kemp's ridley sea turtles in the northwest Atlantic, in which turtles acclimated to warm water become motionless when subjected to sudden cold water.[85]

Increased temperatures make some diseases more prevalent in aquatic organisms, affecting the availability of seafood and increasing seafood-borne diseases. Shell disease in American lobster is associated with changing molting patterns due to spring warming and increased exposure to summer heat.[86] Climate change is expected to cause higher mortality of blue crabs due to infection by *Hematodinium*[87] and *Callinectes sapidus* reovirus 1.[88] Harmful algal blooms occur more often in the Northeast.[89] Evidence links climate change to an increase in the potential growth rates and bloom-season duration of *Margalefidinium polykrikoides*, which kills finfish and bivalve mollusks,[89,90,91] and in the number of blooms of *Prorocentrum minimum*.[92,93] Increasing temperature is linked to increases in the occurrence of pathogens (e.g., *Vibrio* species),[60] which are among the most important causes of seafood-borne diseases.[94]

Increasing water temperature is expected to alter fish and shellfish community structure in estuaries.[95] Significant declines in the relative habitat usage of several economically important finfish species (e.g., Atlantic croaker, spot, and summer flounder) were observed in the Chesapeake Bay from 2008 to 2019,[96] driven in part by the NAO.

The abundance of subtropical species such as pinfish and white shrimp is expected to increase in the Chesapeake Bay and coastal lagoons, whereas more temperate species, such as soft clam and sand shrimp, might decrease.[97,98] In the Chesapeake Bay, an observed increase in the abundance of white shrimp[99] was related to favorable environmental conditions, including rising temperatures. Projections of shorter winter periods and warmer winter temperatures in the Chesapeake Bay suggest that by 2100, blue crabs will grow faster and improve their overwinter survival, increasing the productivity of the population.[100]

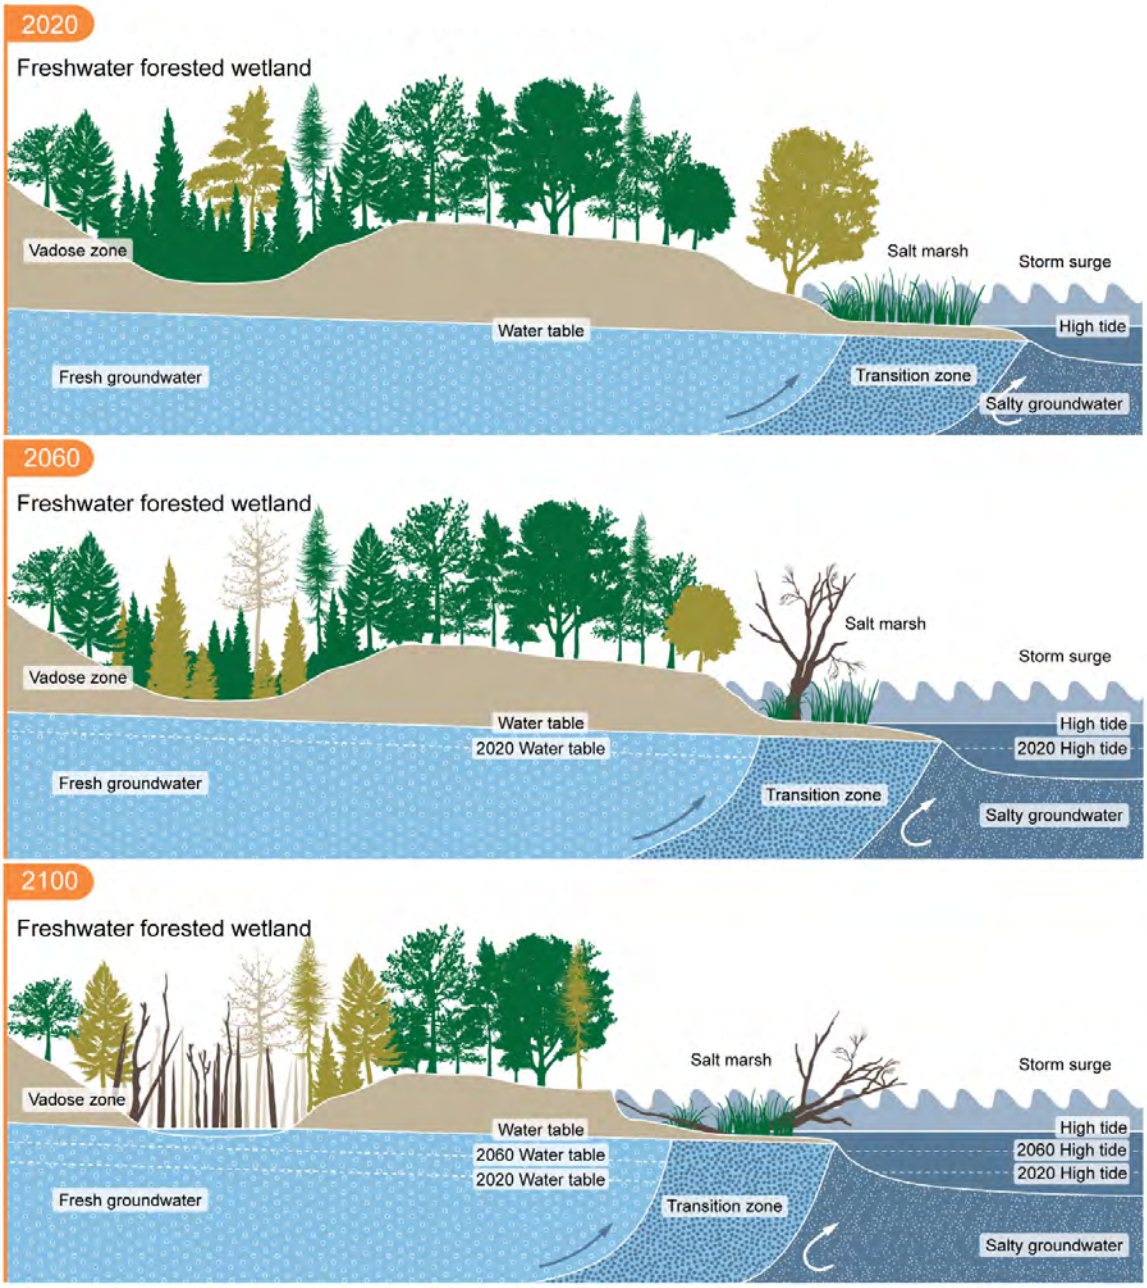
Combined with changes in salinity, ocean acidification exerts stress on shell-building organisms in the region (KM 2.3). The Mid-Atlantic Bight is acidifying faster than other Atlantic coastal regions and the open ocean.[101] Ocean acidification may impact fishery resources, including American lobster, scallops, oysters, clams, and mussels.[102] For example, projections of sea scallop biomass suggest a potential decrease of more than 50% by the end of the century under a very high scenario (RCP8.5) and 13% under an intermediate scenario (RCP4.5).[103] Scallops are one of the most lucrative fisheries in the Northeast, and acidification will have socioeconomic ramifications.

Oxygen loss in ocean and coastal areas, which is correlated with water temperature and nutrient enrichment, is also an important driver of marine ecosystem change (KM 2.3). The rate of change varies by region, with coastal waters of the Northeast showing a drop in oxygenation that outpaces that of the global ocean and broader North Atlantic.[104,105,106] Projected increases in precipitation discussed in Key Message 21.1 will lead to increased runoff and nutrient loading into coastal waters. Estuaries such as the Chesapeake Bay that receive significant amounts of nutrients from the watershed that stimulate algae production experience low oxygen levels (hypoxia),[107] especially during the summer months. Furthermore, temperatures are rising in the region, and in the Chesapeake Bay this is driven by increases in air temperature and in reflected longwave radiation, as well as by warming of the continental shelf.[108] Marine heatwaves are also increasing in frequency, number of days per year, and yearly cumulative intensity in the Chesapeake Bay, which is projected to reach a semipermanent marine heatwave state by 2100, relative to present day.[109] Under such a condition, extreme temperatures will occur for more than six months in a year. Increases in the temperature and intensity of marine heatwaves are expected to decrease the dissolved oxygen content of water and worsen the hypoxic conditions, with consequent negative effects on fish, shellfish, and other living organisms.[110,111]

Sea level rise, tropical and extratropical cyclones, storm surges, and flooding are changing natural coastal wetlands and forests and the species that inhabit them (Figure 21.7; Ch. 9).[112] Impacts of rainfall and riverine floods on coastal areas include shoreline erosion,[113] damage to infrastructure and agriculture, and the degradation and loss of coastal ecosystems, including tidal wetlands and forests (KMs 9.1, 9.2).[114,115] Coastal inundation poses increased risks to aquifers and buried structures, such as septic tanks and pipes, which would degrade water quality.[116] Coastal zone groundwater supplies (such as in Long Island, New York, and Cape May County, New Jersey) are also vulnerable to saltwater intrusion from sea level rise.[117,118]

Coastal forests in the Northeast, such as the Lower Eastern Shore of Maryland and other areas of the Delmarva Peninsula, have been affected by saltwater intrusion and salinization of the soils.[119,120] When coastal forests are invaded by salt water, they transform into tidal marshes, leaving behind standing dead trees, called ghost forests,[121,122] and promoting the growth of *Phragmites australis*, an invasive reed grass that provides less suitable habitats for fishes, crustaceans, and other invertebrates.[123]

Projected Changes in Coastal Forests



Rising sea levels kill trees and transform coastal forests into marshes, damaging vital ecosystems and the services they provide to the community.

Figure 21.7. As sea level rises, the water table also rises; the vadose zone (which is between the ground surface and the groundwater table) becomes thinner, bringing the water table closer to the surface; and tidal flooding and storm surges reach farther inland, resulting in forest dieback and conversion of forested wetlands to standing-water wetlands. Over time, these changes result in permanent habitat shifts. Adapted from Sacatelli et al. 2020.[122]

Advancements in predictive modeling of coastal and marine resources[59,79,124] are informing expectations of future climate-driven changes in the thermal habitat of species, such as American lobster (Figure 21.6) and sea scallops, and enabling marine resource managers to anticipate risks to these fisheries. Projections of habitat changes in the Northeast suggest that sea scallops will undergo a northward shift, while American lobster will move farther offshore over the next 80 years.[125] Information on expected shifts in the distributions of marine resources is important for adaptive actions that can support livelihoods and local economies reliant on these resources.

Adaptation responses to sea level rise and shoreline erosion include the use of natural and nature-based features, such as eco-engineered oyster reefs (e.g., oyster castles), and management and restoration[126,127] of coastal wetlands.[128,129,130] Collaborative learning and exchange of ideas among multidisciplinary groups, including salt marsh professionals, is facilitating salt marsh management and restoration in the region; techniques include using drone technology to monitor living shorelines and constructing and evaluating runnels (shallow, narrow channels used to drain water from the marsh surface at low tide).[131,132,133,134] Other measures are aimed at managing stormwater and reducing carbon dioxide (CO_2) emissions to mitigate ocean acidification.[135]

New England and Mid-Atlantic fishing communities are particularly vulnerable to climate impacts and face declining fishing opportunities unless they adapt, either through catching new species or fishing in new locations.[136] Actions undertaken to reduce potential climate change impacts to Northeast fisheries range from individual actions to changes in federal governance.[137] Fishing patterns such as location and timing have altered in response to shifting species distributions (e.g., summer flounder). Effective adaptation strategies include diversifying species targeted for harvest in response to changing availability and improving fleet mobility, so fishers can follow their target species.[138] Marine heatwaves led to an early influx of molted lobsters, prompting the lobster industry to implement changes throughout the supply chain to avoid price drops should another warm year with early and intense landings occur.[139] However, key barriers to adaptation efforts include fisheries specialization and dependency, fishery access, working waterfront and workforce issues, and management system responsiveness.[140] Furthermore, interactions with threatened and endangered aquatic mammals can complicate adaptation efforts. Changes in right whale patterns due to warming have increased concern about the risk of vessel strikes. This has prompted calls for increased fishing gear regulations, with possible ramifications for the lobster industry.[141]

Key Message 21.3

Disproportionate Impacts Highlight the Importance of Equitable Policy Choices

Extreme heat, storms, flooding, and other climate-related hazards are causing disproportionate impacts among certain communities in the Northeast, notably including racial and ethnic minorities, people of lower socioeconomic status, and older adults (*very likely*, *very high confidence*). These communities tend to have less access to healthcare, social services, and financial resources and to face higher burdens related to environmental pollution and preexisting health conditions (*very likely*, *high confidence*). Social equity objectives are prominent in many local-level adaptation initiatives, but the amount of progress toward equitable outcomes remains uneven (*very likely*, *high confidence*).

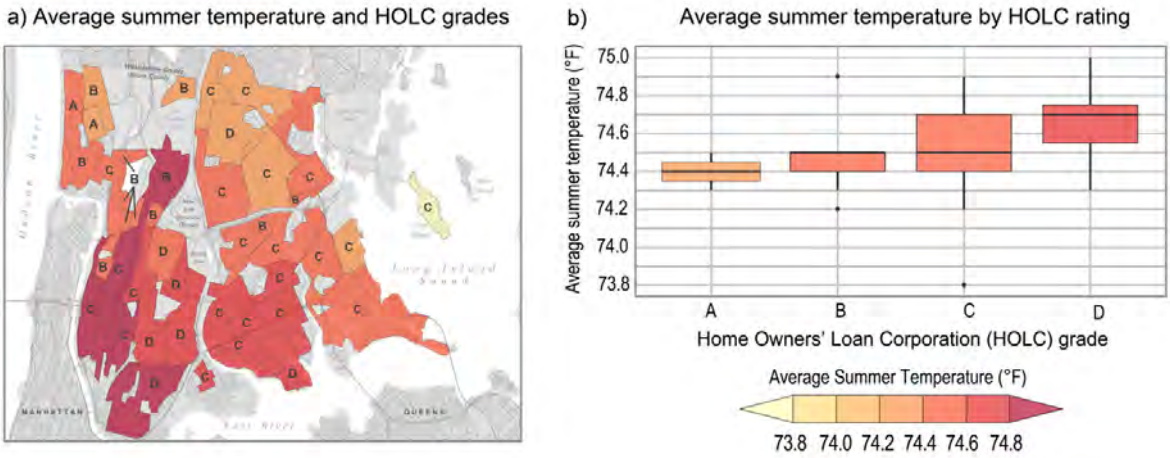
Across the Northeast, the disproportionate impact of climate change and extreme weather on racial and ethnic minorities and low- and moderate-income communities has provided focus to new advocacy and policy work to advance equity and environmental justice.

Climate impacts—including extreme heat, stronger storms, flooding, and pollution—compound the environmental, health, and socioeconomic burdens on some communities (KMs 12.2, 15.2). These burdens include historical racially based injustices such as redlining (a discriminatory practice by which financial products such as loans and insurance were refused or limited in specific geographic areas),[142,143,144,145,146] land dispossession and forced migration of Indigenous Peoples, and disinvestment in poor communities and communities of color. In response, local, Tribal, and state governments are increasingly working directly with community organizations, Indigenous Peoples, and environmental justice groups to develop new approaches to these challenges.

Analyses of summer land surface temperature and sociodemographic data reveal heat exposure disparities across Northeast neighborhoods. Specifically, neighborhoods with higher proportions of racial and ethnic minorities, people of lower socioeconomic status, and households without automobile access experience higher temperatures.[147]

Relative to non-redlined neighborhoods, historically redlined areas in the Northeast show consistent city-scale patterns of elevated land surface temperatures.[148] For instance, Figure 21.8 shows higher average summer temperatures in redlined neighborhoods in the Bronx, New York. People of color tend to live in census tracts with higher surface urban heat island intensity than non-Hispanic Whites, and this difference is particularly pronounced in the Northeast.[149] Across the United States, higher heat is experienced by racial and ethnic minorities in metropolitan statistical areas more segregated from Whites and in census tracts with lower socioeconomic status and higher percentages of Black and Asian residents.[150]

Summer Temperature Differences by Neighborhood in the Bronx, New York



Average summer temperatures are generally higher in historically redlined neighborhoods in the Bronx, New York.

Figure 21.8. Historically redlined areas, defined by lower Home Owners' Loan Corporation (HOLC) grades that deprived certain areas of federal loans and insurance, typically show higher temperatures relative to non-redlined neighborhoods, leading to greater likelihood of heat exposure for areas with lower socioeconomic status and higher percentages of racial and ethnic minorities in the Bronx, New York (1981–2010). The letters A, B, C, and D on the figure correspond to the four categories used by the HOLC: "Type A (Best), Type B (Still Desirable), Type C (Declining), and Type D (Hazardous)."[143] Figure credit: Union of Concerned Scientists, RAND Corporation, Columbia University, NOAA NCEI, and CISESS NC.

Compared with the historic territories of Indigenous Peoples, present-day Tribal lands experience nearly two additional extreme heat days per year and a decrease of nearly 23% in annual average precipitation.[151] For some members of Tribal Nations across the Northeastern US, climate change impacts on Tribal reservation or trust lands, which in some Tribal Nations have been reduced to 1 square mile or less, pose serious threats to Tribal cultures. One of the greatest threats will be the shifting of ecosystems and species migration beyond Tribal lands or regions.[152] Loss of access to culturally significant locations harms the physical and mental health of Indigenous Peoples (KM 15.2).[153]

Temperature extremes are related to a larger fraction of cardiorespiratory deaths in the Northeast and industrial Midwest (compared with other regions), particularly in areas with higher urbanization, more older people, fewer White residents, and lower socioeconomic status (Zhang et al. 2019).[154] Reasons for the regional differences are unclear. Nationally, health impacts of temperature extremes often cluster in neighborhoods that are also poor, racially segregated, historically disinvested, and suffer other environmental problems such as air pollution.[155]

As extreme events become more frequent or severe in the Northeast, both rural and urban fenceline communities (those adjacent to industrial facilities) are expected to face increased health burdens from exposure to toxic pollution and stress related to potential chemical releases (KM 20.3).[156] In rural Pennsylvania, fenceline communities near oil and gas extraction activities show higher pediatric asthma and genital and urinary problems in non-elderly women; increased asthma is related also to industrial animal pollution.[157] Power sector carbon mitigation policies focusing on aggregate emissions reductions (e.g., Regional Greenhouse Gas Initiative) may not redress disparities in pollutant burdens.[158]

Energy insecurity is a complex problem influenced by social determinants of health and the changing climate. Energy burden—the fraction of household income spent on energy costs—varies among racial

groups, depending on energy type, end-use demand, and region, given differences in climate and households' socioeconomic characteristics. The cold Northeast climate leads to higher household energy burdens (compared with the Midwest, West, and South) based on residential energy consumption.[159] African American households had a heavier energy burden than others, but their energy poverty rate (the share of households paying a disproportionate share of income on the cost of energy use) decreased over time, whereas the rate for White households increased. Despite the substantial impact that energy burden can have on population health, links with climate change have been understudied.[160]

Continued warming in the Gulf of Maine ecosystem (KM 21.2) threatens access to species and locations of cultural significance. Some Tribal Nations and other coastal communities may have to shift their economic or subsistence harvests to new species that are migrating to the region, but the loss of other species or places is expected to result in a loss of cultural lifeways that will harm physical and mental health and well-being.[161]

Managed relocation from flood-prone areas is still relatively uncommon (KM 20.3), but initiatives such as the New Jersey Department of Environmental Protection's Superstorm Sandy Blue Acres Buyout Program are combining federal and state funding to support community relocation. Demand for buyouts (where homeowners sell properties to the government and the land is restored to open space) along the Mid-Atlantic seaboard relates to household-level perceptions of risk and confidence in ability to adapt to changing conditions.[162] Buyouts by local governments tend to be more common in counties with larger populations and income.[163] However, bought-out properties tend to be concentrated in areas of greater social vulnerabilities within the counties (i.e., relatively poorer, less densely populated areas with lower levels of education and English language proficiency and with greater racial diversity). The reasons underlying this pattern are unclear, but the finding highlights the need for evaluating the equity of buyout implementation and outcomes (KM 22.1).[164]

Social equity objectives that address challenges facing low-income communities and communities of color are prominent in local-level adaptation plans and initiatives.[165] These groups are less likely to have access to socioeconomic or healthcare resources to mitigate climate change impacts and are more likely to have preexisting health concerns, greater sensitivity to environmental changes, and higher exposure to pollution.[166]

Three dimensions of social equity are important in understanding uneven climate-related burdens. Distributive equity refers to the fair distribution of risks and benefits across groups; procedural equity focuses on the inclusion of affected groups prior to and during decision-making processes; and contextual equity reflects the preexisting structural, political, and socioeconomic conditions.[167,168]

Distributive equity has been a prominent theme in New York City's planning initiatives (e.g., OneNYC 2050). These plans cited the disproportionate health impacts of extreme temperatures on certain populations and focused heat mitigation investments on developing green space in underserved neighborhoods.[169] Local legislation mandated that city agencies work together and with local environmental justice leaders (addressing procedural equity) to publish more data on local environmental conditions, study environmental justice concerns, and publish a first-ever environmental justice plan that embeds a new approach to decision-making to counter historic injustices.[170,171] When representatives of frontline communities are included in the decision-making process (which helps address procedural equity), more attention is paid to the equitable distribution of benefits and burdens.[165]

Innovative sea level rise adaptation strategies developed by Tribal Nations, such as the WAMPUM Indigenous adaptation framework (Box 21.2), reflect Indigenous Knowledge typically not evident in other existing sea level rise adaptation frameworks in the Northeast.[172] Nonetheless, even when Tribal Nations work across jurisdictions to address climate change impacts, some adaptation plans do not take into

account Tribal Nations' interests in natural resources and areas of cultural significance. Tribal Nations face difficulties if adaptation strategies require relocating or reacquiring lands with access to cultural resources.[153] Relocation is a profoundly sensitive concern for Tribal Nations, given the history of forced migration and loss of homeland access. These past injustices highlight the importance of the United States' meeting trust and treaty obligations to Tribal Nations and ensuring that rights and access to original homelands, waters, and coasts are maintained and protected, even if these places become submerged.[152]

Key Message 21.4

Climate Action Plans Are Now Being Implemented

In recent years, there have been substantial advances in the magnitude and scope of climate action across all jurisdictional scales (*high confidence*). Almost every state in the region has conducted or updated a climate impact assessment, developed a comprehensive climate action plan, and enacted climate-related laws since 2018 (*high confidence*). Innovative approaches to transparent, inclusive, and equitable processes around climate action are being embraced by Tribes, municipalities, and states (*high confidence*). Although ambitious emissions reduction targets have been put forward, meeting these goals is expected to be challenging (*medium confidence*).

The landscape of climate action in the United States has been dynamic in recent years. The United States' withdrawal from and rejoining of the Paris Agreement raised questions among international and subnational constituencies about America's ability to meet its mitigation targets—and, as a consequence, catalyzed substantial climate action at state, city, business, and Tribal levels.[173,174] Moreover, the increase in public concern about community climate risks has led to a proliferation of vulnerability assessments and resilience plans among these subnational jurisdictions.[175]

A compilation of recent state-level climate impact assessment reports, climate action plans, and relevant laws and executive orders for the 12 states (plus Washington, DC) of the Northeast is shown in Table 21.1. For a more comprehensive assessment, see, for example, Dalal and Reidmiller (2023),[176] the US Climate Alliance inventory of member state policies particularly around mitigation,[177] the Georgetown Climate Center's State Adaptation Progress Tracker,[178] and the Northeast Region reports section of NOAA's Climate Resilience Toolkit.[179] The intent in presenting the information in this Key Message is to provide the ever-growing regional workforce (and related volunteer efforts) focusing on climate action planning and implementation with a concise, accessible source of information and inspiration as these workers develop, refine, and/or update their own assessments, plans, and climate-related laws. It endeavors to be a decision-support tool. An analysis of individual vulnerability assessments, climate action plans, or climate laws and executive orders is beyond the scope of this chapter; rather, the utility comes from providing—for the first time ever—a single resource compiling all of the Northeast's state- and Tribal-level information in one place. For a more comprehensive look at state-level climate mitigation policies across the entire country, see Key Message 32.5.

The Regional Greenhouse Gas Initiative (RGGI) is the largest regional climate coordination effort in the Northeast. RGGI includes every state in the Northeast region except West Virginia, but as of this writing, Pennsylvania's membership is undergoing a legal challenge. Established in 2005, RGGI was the Nation's first mandatory, market-based cap-and-trade program aimed at reducing CO_2 emissions from the power sector. RGGI issues a limited number of tradable CO_2 allowances with member states, which are then able to distribute the allowances through quarterly auctions. The revenue generated through these auctions goes toward investments in energy efficiency, renewable energy, and other consumer benefit programs. Although

there have been critiques of RGGI for, among other things, not adequately integrating environmental justice considerations (e.g., Declet-Barreto and Rosenberg 2022[158]), it has also been estimated that the program is responsible for an annual reduction of almost 5 million metric tons of CO_2[180] across the regulated states—roughly equivalent to the annual residential CO_2 emissions from Rhode Island and Maine combined.[181,182]

There has been strong cross-jurisdictional collaboration between the federal and state governments to advance climate resilience in the past few years. An example of this is the Federal Highway Administration's Resilience and Durability to Extreme Weather Pilot Project. Under this effort, departments of transportation and metropolitan planning organizations from eight states in the Northeast (ME, MA, CT, NY, NJ, PA, DE, and MD) are performing detailed vulnerability assessments to understand the condition of their transportation-related assets and the risks they face from climate change (KM 13.1).

In many Northeast states, particularly in New England, mitigation and adaptation action has been solidified in state law. Many states in the region have legally mandated greenhouse gas emissions reductions by midcentury, consistent with the goals of the Paris Agreement, and require state agencies to integrate the best available science (e.g., sea level rise projections) into land-use planning and zoning, building codes, and regulation development. Seven states in the region (ME, VT, MA, RI, CT, NY, and NJ) have laws requiring emissions reductions of at least 80% by 2050 (usually against a 1990 baseline). Several go even further in calling for economy-wide carbon neutrality before midcentury. Most of these laws have been passed by state legislatures since 2018. In other Northeast states, much of the action has been promulgated through executive order.[176]

Below are some novel climate actions employed by states in recent years that reflect increased attention to economic risks; equity considerations; and transparent, inclusive engagement processes (e.g., Molino et al. 2020;[183] Powell et al. 2019;[184] Reckien and Petkova 2019[185]). The list is illustrative, not exhaustive, but provides practitioners with examples of the latest innovative ways of advancing climate action at the state level.

- In Maine, the work of the Maine Climate Council and its Maine Won't Wait climate action plan was informed by a collection of economic impact and opportunity reports,[186] as well as an equity assessment conducted by an external team of experts.[187]
- In Massachusetts, a climate bill was passed that mandates that all new vehicles sold be zero emissions by 2035, as well as pilots a program allowing municipalities to ban fossil fuel connections (such as natural gas lines) to new construction.[188]
- Among other provisions, Rhode Island's H5445 requires the integration of environmental justice into climate action planning efforts to reduce impacts on vulnerable communities and create an equitable transition.[189]
- A Connecticut law allows municipalities to create stormwater authorities charged with developing stormwater management and public outreach.[190] Connecticut also enacted a first-in-the-Nation climate risk provision requiring the state insurance commissioner to submit a report on progress toward addressing climate-related risks, monitoring greenhouse gas levels, and bolstering resilience of insurers to the physical impacts of climate change.[191]
- In New York, the Climate Leadership and Community Protection Act established a Climate Justice Working Group to support the Climate Action Council in mainstreaming environmental justice considerations.[192] The New York State Common Retirement Fund released a Climate Action Plan Progress Report highlighting the fund's recent efforts to address climate risks and opportunities.[193]
- In New Jersey, a study was commissioned to better understand the integration of the needs and challenges of underrepresented and socially vulnerable populations into coastal hazards planning.[194]

- Maryland launched a Climate Leadership Academy in 2018, providing standardized climate training and support to state and local government officials, citizens, the private sector, and nonprofit organizations.[195]

Table 21.1. Recent Climate Planning and Action Among States and Tribal Nations in the Northeast

The table is a compilation of state and selected Tribal climate impact assessments and action plans, alongside illustrative climate-related laws, since 2018.

State	Climate Impact Assessment	Climate Action Plan	Climate-Related Laws
Maine	Scientific Assessment of Climate Change and Its Effects in Maine[196] Maine Climate Science Update 2021[197]	Maine Won't Wait[198]	An Act to Analyze the Impact of Sea Level Rise[199] An Act to Implement Agency Recommendations Relating to Sea Level Rise and Climate Resilience[200] An Act to Establish a Pilot Program to Encourage Climate Education in Maine Public Schools[201]
New Hampshire	New Hampshire Climate Assessment 2021[202]	N/A (The state has a pre-2018 climate action plan[203])	An Act Establishing a Coastal Resilience and Economic Development Program[204]
Vermont	Vermont Climate Assessment 2020[205]	Initial Vermont Climate Action Plan[206]	Global Warming Solutions Act[207]
Massachusetts	Massachusetts Climate Change Assessment[208]	Massachusetts Clean Energy and Climate Plan for 2025 and 2030[209] Massachusetts State Hazard Mitigation and Climate Adaptation Plan[8]	An Act Creating a Next-Generation Roadmap for Massachusetts Climate Policy[210] An Act Driving Clean Energy and Offshore Wind[188]
Rhode Island	Resilient Rhody: The Statewide Climate Resilience Action Strategy[211] Rhode Island 2022 Climate Update to the 2016 GHG Emissions Reduction Plan[212] Executive Climate Change Coordinating Council (EC4) to deliver "2025 Climate Strategy" by Dec 31, 2025	Resilient Rhody: The Statewide Climate Resilience Action Strategy[211] Rhode Island 2022 Climate Update to the 2016 GHG Emissions Reduction Plan[212] Executive Climate Change Coordinating Council (EC4) to deliver "2025 Climate Strategy" by Dec 31, 2025	2021 Act on Climate[189]
Connecticut	Connecticut Physical Climate Science Assessment Report[213]	Taking Action on Climate Change and Building a More Resilient Connecticut for All[214]	An Act Concerning Climate Change Adaptation[190] A provision to address climate-related risk to insurance[215]

State	Climate Impact Assessment	Climate Action Plan	Climate-Related Laws
New York	Observed and Projected Climate Change in New York State[216]	Draft Scoping Plan[217] New York State Climate Action Council Scoping Plan[218]	Climate Leadership and Community Protection Act[192] Soil Health and Climate Resiliency Act[219] Green CHIPS[220] Environmental Bond Act[221]

Box 21.1. Innovative Approaches to Climate Action at the Municipal Level

To complement the aforementioned focus on state-level planning and implementation—a jurisdictional level that was feasible to assess within the scope of this chapter—this box highlights examples of innovative approaches to climate action within mid-sized cities of the Northeast region. While extensive climate action planning and implementation has occurred within the major metropolitan areas of the Northeast region (e.g., Boston,[247] New York City,[169] and Philadelphia[248]), the focus here is on a geographically, economically, and politically diverse sampling of mid-sized cities that have different capacities (e.g., specialized staff, funding) to commit to the issue. Their efforts generally receive less visibility, but the need among similarly sized cities in the region—to learn about best practices and lessons learned in developing and implementing climate action plans to inform their own efforts—can be significant.

Cross-Jurisdictional Climate Action Planning in Portland and South Portland, Maine

The cities of Portland and South Portland, Maine, are jointly producing assessments and plans to address climate change. The Climate Change Vulnerability Assessment report highlights the ways climate change is projected to affect Portland and South Portland, and the Our Contributions to Climate Change report contains data about their greenhouse gas emissions sources.[249,250] Informed by these foundational reports, the *One Climate Future* climate action and adaptation plan commits the two cities to reduce their greenhouse gas emissions by 80% from the 2017 level by 2050,[251] with municipal operations running on 100% renewable energy by 2040. Both city councils prioritize implementing the plan, working closely with municipal staff, business leaders, nonprofit organizations, and concerned citizens to ensure equitable and transparent progress is being made.

Pittsburgh Climate Action Plan 3.0 and State of Sustainability Reports

Pittsburgh places climate action at the forefront of its municipal agenda through executive orders and planning efforts. Mayor William Peduto signed Executive Order 2017-08, in which the City of Pittsburgh endorsed and expressed its commitment to the "principles" of the Paris Agreement.[252] An executive order in April 2021 commits Pittsburgh to achieve carbon neutrality by 2050.[253] The city released an updated Climate Action Plan 3.0 in 2017, showcasing progress and adding new mitigation and adaptation measures.[254,255] The update process included multiyear civic engagements bringing together residents, the business community, the nonprofit sector, and local, state, and federal government partners.[256] The plan recognizes that climate-related stressors disproportionately affect some of the city's most vulnerable residents and focuses on co-benefits including improved equity. The city tracks progress through its Pittsburgh Equity Indicators report and produces annual State of Sustainability reports, highlighting progress on the Climate Action Plan.[257] The city's recently updated stormwater code requires new developments to reflect a future-climate-projected 10-year rainfall event instead of historically derived estimates.[258]

Morgantown, West Virginia, Municipal Green Team Strategic Plan

While West Virginia has no formalized state-level mitigation or adaptation plan, the city of Morgantown committed to the Paris Agreement goals in August 2017. The Green Team, established in 2007, recommends actions to achieve the emissions-reduction goal,[259] advises the city council on environmental sustainability, and produces annual reports on the status of team projects.[260] In 2018, the Green Team released the Morgantown Municipal Green Team Strategic Plan (2018–2022), which contains a framework of goals and objectives that it plans to accomplish, including creating a climate action plan.[261] Lastly, the team has an energy policy guide, which contains recommendations to reduce the cost of energy and also highlights the costs of fossil fuel extraction and combustion on the environment, human health, and national security.[262]

Box 21.2. Tribal Nations Leading and Setting an Example

WAMPUM Adaptation Framework

The WAMPUM Adaptation Framework is a culturally responsive approach developed by Shinnecock Indian Nation citizen Dr. Kelsey Leonard for Northeast Indigenous Peoples impacted by sea level rise. This framework provides adaptation actions drawing from coastal Tribal Nations' Indigenous Knowledge systems. WAMPUM is an acronym for Witness (climate change warnings), Acknowledge (cultural relationships with land and water), Mend (areas damaged by sea level rise), Protect (cultural sites for future generations), Unite (with other Tribal Nations), and Move (to places out of harm's way but with cultural connections). The framework connects to wampum (carved quahog and whelk shells), which Tribal cultures in the Northeast have used for millennia for establishing diplomatic relations, documenting kinship, recording treaties, and negotiating the economic systems of settler European nations as currency. The WAMPUM framework acknowledges that sea level rise may force some Tribal nations and communities to relocate; however, the framework insists on Tribal self-determination in movement and continued rights, access, and cultural connections with areas inundated by sea level rise.[172]

Climate Change Adaptation Plan for the Akwesasne/Saint Regis Mohawk Tribe

The Saint Regis Mohawk Tribe was the first Tribal Nation in the Northeast to formally draft a climate change adaptation plan, which was published in 2013. The plan was initiated by the Tribal Nation's Environment Division to investigate the local impacts of climate change and to provide recommendations for adaptation actions. This plan continues to be implemented and is noted for its grounding in the cultural framework and priorities of the Saint Regis Mohawk Tribe.[245]

Shinnecock Indian Nation Climate Vulnerability Assessment and Action Plan

Shinnecock translates to "People of the Stony Shore." The Shinnecock Indian Nation, located on eastern Long Island, completed a climate change adaptation plan following Hurricane Sandy and updated it in 2019. The Shinnecock Indian Nation has a 1-square-mile reservation with more than 600 residents; it is vulnerable to sea level rise, storms, flooding, and coastal erosion. Other climate change concerns include water quality issues from increasing temperatures, salinity changes, and acidification. The Shinnecock are closely tied to the coast, and fish and shellfish have been a staple of traditional diets for thousands of years.[51] The updated Shinnecock Indian Nation Climate Vulnerability Assessment and Action Plan includes several steps, including evaluation of adaptation actions, habitat restoration, green infrastructure projects, land conservation, and outreach and education on climate change.

Mi'kmaq Nation: Thirteen Moons Climate Change Adaptation Plan

The Mi'kmaq Nation is one of several Tribal Nations of the Wabanaki Confederacy ("People of the Dawn"). The Mi'kmaq Nation (formerly known as the Aroostook Band of Micmacs) live in northern Maine in Aroostook County. In February 2022, the Tribal council approved its Thirteen Moons Climate Change Adaptation Plan. The primary concern for the Mi'kmaq Nation is warming winters, which are encouraging the spread of invasive species that damage forest health (e.g., emerald ash borer) and harming animal populations (e.g., winter tick impact on moose). The plan calls for proactive efforts to address climate change, such as the development of solar energy, community education and outreach on climate change, and forest and wildlife health monitoring.[246]

Key Message 21.5

Implementation of Climate Plans Depends on Adequate Financing

Options for financing mitigation and adaptation efforts have expanded in recent years, providing households, communities, and businesses with more options for responding to climate change (*high confidence*). Flood insurance allows individuals and communities to recover following extreme flooding events, but many at-risk homeowners lack adequate coverage (*high confidence*). Although the public sector remains the primary source of funding for adaptation, private capital has started to invest in a variety of mitigation and adaptation projects, including services for monitoring climate risks and community-based catastrophe insurance (*high confidence*).

Climate adaptation plans and resilience projects ultimately need financing to come to fruition. Although finance is just one piece of the climate adaptation puzzle, progress and innovation in recent years have expanded the options available to businesses, communities, and Tribal organizations to cover the cost of building resiliently for the future.[263] Implementing adaptation plans also requires meeting prerequisite conditions. Political leadership and local trust must be built among all stakeholders to ensure a common vision and successful outcome, and technical expertise is needed to execute the plan.[264] Sources of private capital also look for transparency, well-defined risk metrics, and an adequate return on investment.[265]

Successful projects often require a mix of funding sources, and financing via a mixed or stacked approach becomes increasingly necessary as project size grows (KM 31.6).[266] A stacked approach also helps spread the burden and benefits across multiple parties to achieve mutually beneficial mitigation and adaptation goals, improved distribution of risk management functions, and increasing private equity participation in climate adaptation activities.[265]

Currently, access to private funding of climate mitigation and adaptation remains primarily limited to large businesses and institutional investors, as their focus remains on protecting corporate investments and limiting potential liability, not the equitable distribution of climate mitigation and adaptation funds.[267] Federal and state public funding of climate mitigation and adaptation—whether via grants, loans, or tax assessments—is currently available to a wider array of stakeholders and is more readily accessible to over-burdened communities (e.g., EPA 2023[268]).

For households and businesses, property insurance remains one of the most effective risk financing mechanisms for protection from both natural catastrophes and the impacts of climate change.[269] Insurance provides individuals, businesses, and communities a source of financial resilience from natural disasters, annually providing billions of dollars in recovery funds to devastated communities across the United States.[270] Despite paying approximately $661 billion (in 2022 dollars) in insurance claims from natural disasters between 2012 and 2021, the US property and casualty insurance industry remains very well capitalized, with a record $978 billion (in 2022 dollars) in policyholder surplus to pay claims from future catastrophic events.[271]

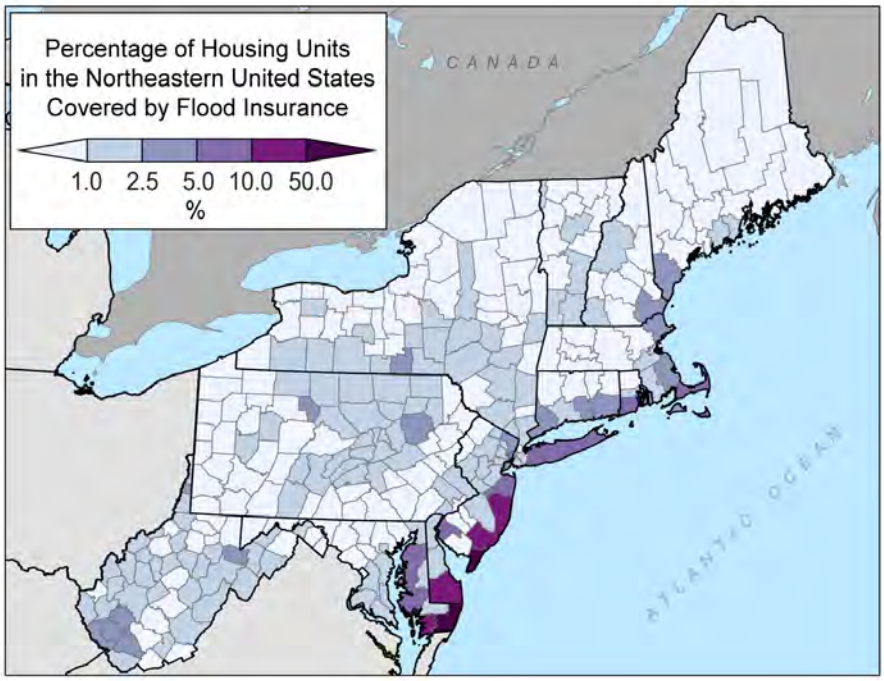
However, insurance take-up rates (the percentage of households who purchase insurance) vary greatly by natural hazard. While about 50% of fire and wind damage in the United States is covered by insurance, only 12%–14% of flood damage is insured by the federally run National Flood Insurance Program (NFIP).[272] This "gap" in flood insurance coverage leaves millions at risk of financial hardship as the frequency and severity of coastal and rainfall flood events across the Northeast are expected to increase (KM 21.1).[273] In 1978–2015, 6 of the top 17 states with the highest NFIP payouts were in the Northeast, with New Jersey and New York ranked third and fourth, respectively.[274] Currently only two counties in the Northeast have flood insurance

take-up rates above 50%. No other northeastern county exceeds 20% take-up, averaging 6.5% along the coast and 1.3% inland (Figure 21.9).

Lack of flood insurance coverage is driven by affordability issues and the underestimation of flood risk by individuals. Misperceptions around FEMA flood maps play a significant role here, as most individuals are unaware that the maps are not holistic in their assessment of flood risk. While FEMA is updating maps, some are still decades old and unrepresentative of total flood risk. Additionally, the maps do not consider flood risk along smaller catchments, nor do they consider the potential for localized flooding from intense rainfall events.[275] Flood risk data for overburdened and Tribal communities have historically been underrepresented in flood mapping as well (KMs 16.1, 20.1). Since flood insurance is not required by mortgage lenders outside of mapped FEMA-designated Special Flood Hazard Areas (SFHAs; locations with an annual probability of flooding of 1% or more), many homeowners in non-mapped SFHAs or prone to flash flooding believe that they are not at risk and thus forego coverage.[276]

Even for those who purchase NFIP coverage, policy limits are capped by law at $250,000 for residential structures, well below the current median value for an existing single-family dwelling in the Northeast ($366,000), potentially leaving policyholders financially exposed if their homes are completely destroyed.[277,278] Enforcement of flood insurance requirements is another issue, as lenders often do not continue to verify coverage in locations where flood insurance is required; as a result, about one-third of policyholders stop purchasing coverage after three years.[279]

Flood Insurance Take-Up Rates by County



Many Northeast households and communities risk financial hardship from a lack of flood insurance coverage.

Figure 21.9. The figure shows flood insurance take-up rates by county in the northeastern United States, based on 2020 Census housing units and active National Flood Insurance Program policy counts at the end of 2021. Almost half of the counties in the region have less than 1% market penetration, while only two counties (Cape May, New Jersey, and Worchester, Maryland) have more than 50% of their housing units insured for flood. The lack of coverage, particularly inland, leaves both individuals and communities at risk of major financial hardship after a flood event. Figure credit: Munich Reinsurance America Inc.

Because of major flooding events associated with hurricanes—including Irene, Sandy, and Ida in the Northeast—NFIP remains more than $20 billion in debt to the US Treasury, despite $16 billion in debt forgiveness by the federal government in 2017. This debt is driven by the program's concentration of vulnerable risks along the coast and subsidized premiums that were unable to cover the claims volume from multiple large flood events.[280] In response, the NFIP has developed a new pricing methodology, Risk Rating 2.0, with a goal of making premiums better reflect the level of flood risk at individual locations.[281] Additionally, the NFIP started purchasing catastrophe reinsurance in 2017 and catastrophe bonds in 2018, which together can provide more than $1 billion in claims-paying capacity if losses to the NFIP exceed $10 billion from an extreme flood event.[282]

Under the new Risk Rating 2.0 system, the majority of NFIP policyholders were projected to see only a nominal change in premiums, with only 4% of policyholders expected to see larger increases.[281] However, the move toward risk-adequate rates exacerbates affordability issues, especially for vulnerable individuals and communities (KM 9.3). To address rising costs, some states have used public funds to help individuals in vulnerable communities afford flood insurance. For example, in 2019, the state of New York reduced property taxes for lower-income households to make flood insurance more affordable.[263] Private insurers, who mostly stopped underwriting flood insurance for homeowners and small businesses in 1968, are also starting to reenter this market as more sophisticated flood risk assessment tools become available.[283]

Beyond flood insurance, private-sector financing of climate mitigation and adaptation has increased by 13% globally since 2018, with an annual average expenditure of $332 billion (in 2022 dollars). Of that total, about $85 billion (in 2022 dollars) has been invested annually in the United States and Canada. However, the vast majority of this private capital, nearly 98%, is currently being spent on mitigation, focused on solar and onshore wind energy development, electric vehicle infrastructure, and increasing adoption of electric vehicles.[264]

The current dearth of private-sector investment in climate adaptation, despite ample capital available for such projects, is the result of several business obstacles, including a lack of localized climate data on which to make sound investment decisions, a lack of well-defined performance metrics, and the perception that returns on investment from adaptation projects are insufficient.[265] It also can be challenging for private investors to identify climate adaptation projects that might be financially attractive to them, and, similarly, communities might not know how to find sources of private capital.[264]

Although the private sector's direct investment in climate adaptation remains small, the sector is playing an increasing role in enabling adaptation. Over the past four years, dozens of companies have started providing climate adaptation services, including high-resolution risk assessments, the deployment of sensors for risk monitoring, and innovative finance and risk transfer mechanisms.[265] This private sector investment in adaptation not only helps others but also ultimately makes businesses' own supply chains more resilient to potential climate shocks (Focus on Risks to Supply Chains).[265]

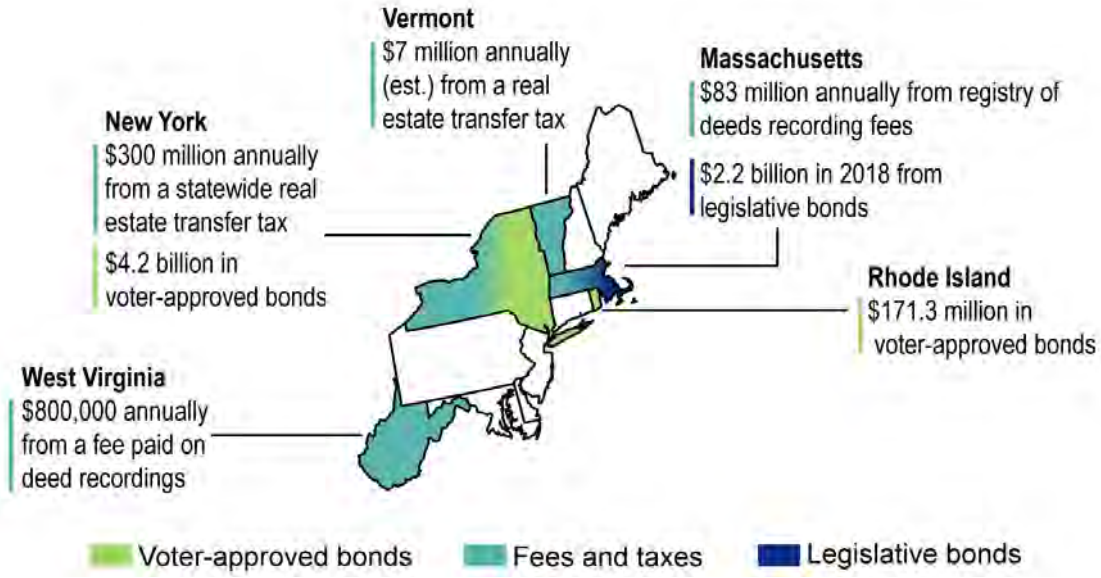
Recent innovations around the financing of climate adaptation by the private sector include community-based catastrophe insurance (CBCI), climate adaptation as a service, and climate investment intermediaries. A CBCI is a community institution (it does not have to be governmental) that helps its members access and afford insurance. The level of involvement by the community institution can vary, from purchasing a group policy on behalf of its members, to creating its own risk-bearing entity, to simply facilitating access to insurance for its members.[263] Climate adaptation as a service allows for the longer-term financing of climate adaptation projects for businesses and communities, with investors repaid over time with interest. Climate investment intermediaries are entities that facilitate matching asset owners with investors interested in climate adaptation projects.[284]

The public sector has historically shouldered the costs related to investments in the built environment.[285] State and local governments are the primary owners and operators of transportation and water systems, spending $216.5 billion on projects in 2019, substantially more than federal spending at $173.3 billion (both amounts in 2022 dollars).[286] The investments represent the responsibility of local entities to ensure continuous operation and services provided to taxpayers.

Providing these services becomes increasingly difficult when dealing with an aging and inefficient infrastructure coupled with climate change. This challenge is highlighted in the American Society of Civil Engineers' 2021 America's Infrastructure Report Card, in which no Northeast state received a grade higher than C.[287] Additionally, state and local officials are finding it challenging to proactively address resilience planning due to limited staff and inconsistent budgeting.

Historic levels of federal funding directed to states, counties, Tribes, and communities through pandemic relief provide access to needed capital for climate resilience. The Infrastructure Investment and Jobs Act of 2021 provides funding through low-interest loan programs such as the Clean Water and Drinking Water State Revolving Funds.[288] Capacity barriers exist to accessing federal funds, especially for Indigenous Peoples (KM 16.2). Increased capacity across these state-administered loan programs and access to grants create opportunities for Northeast states to address deferred maintenance and accelerate project implementation. Additionally, states in the Northeast continue to issue general obligation bonds through statewide ballot measures to finance climate resilience projects (Figure 21.10). Success of voter-approved bonds requires diverse stakeholder engagement. For example, land trusts are uniquely positioned in the Northeast to be effective in quickly generating support from landowners to elected officials for climate adaptation and mitigation funding and projects.[289]

Public Funding for Resilience



Northeastern states provide funding for resilience efforts in a number of ways.

Figure 21.10. Northeastern states fund planning and implementation of resilience projects through multiple public financing mechanisms. Examples of voter approved bonds, taxes and fees, and legislative bonds established and ongoing since 2018 are highlighted. The most common source of state funding originates from annual fees and is largely directed to conservation and natural and working lands. Infrastructure projects and capital investments are most often funded through voter-approved general obligation bonds, with Rhode Island being the most active issuer of bonds for climate-resilience projects. Figure credit: Rhode Island Infrastructure Bank.

While access to infrastructure financing is increasing, the public sector's ability and willingness to repay debt financing is a common challenge. This is heightened by the influx of federal stimulus funding, as well as local governments waiting for potential grant funds. New and innovative financing models that spread credit risk across multiple payors and focus on outcomes have moved from concept to reality. Most deals have focused on stormwater investments to increase installation of nature-based solutions and address regulatory compliance. For example, the Buffalo Sewer Authority financed nature-based solution projects through a $54 million environmental impact bond to support the city's Rain Check 2.0 initiative.[290] Buffalo Sewer will utilize bond proceeds for the design, engineering, and construction of stormwater projects that should reduce combined sewer overflows, improving water quality and community resilience.

As Northeast states plan investment priorities, a pipeline of climate-resilience projects often does not exist. However, there have been recent examples of leadership in Massachusetts, Maine, and Rhode Island to create programs focused on identifying and prioritizing resilience projects. These programs have generated more than $130 million (in 2022 dollars) in state-directed funding for planning and resilience projects from 2018 to 2022. The overall need identified through these planning programs far outweighs the grant funding available and highlights the opportunity to link these priorities with other financing programs.

Traceable Accounts

Process Description

Chapter leadership compiled a list of previous Fourth National Climate Assessment (NCA4) authors and those provided to chapter leadership through the USGCRP author nomination process. They defined potential themes for the region based on their own and potential author expertise, NOAA engagements over a decade in the region via Regional Climate Services, and a literature review. They prioritized invitations to author candidates based on their ability to address potential themes and a desire for diversity based on a mix of regional distribution, career stage, gender, sector, discipline, race, and ethnicity. Where gaps existed, chapter leadership identified additions to the candidate list through professional networks, research into departments at key regional institutions, and searches on several databases of experts from frontline communities. Introductory conversations were pursued to gauge interest and answer questions. In some cases, when author candidates indicated they could not participate, chapter leadership asked them for recommendations of additional candidates.

Author meetings were held on a weekly basis throughout the process, with a Gantt chart used to track tasks and interim milestones. Authors were divided into teams based on expertise and Key Message, and some held team meetings in addition to the full chapter meetings. The author team used productivity tools to gain consensus on key themes for the Zero Order Draft. A public workshop on January 26, 2022, was held virtually, with productivity tools used to synthesize public input provided. Key Message teams then used workshop input and literature review to further develop their Key Messages and develop figures.

Key Message 21.1

Chronic Impacts of Extreme Weather Are Shaping Adaptation and Mitigation Efforts

Description of Evidence Base

Literature reviewed (gathered by using tools such as the Web of Science) discussed an increase in extreme events in the region and the impacts caused by these events.[10,11,12,21] Authors anchored their understanding of climate trends, likelihood, and confidence in climate data analysis through discussions with the Chapter 2 author team and the Technical Support Unit (TSU) science team. Authors frequently referenced descriptive statistics and graphs from the NCA Figure and Climate Data Generator, developed by the TSU, and from NOAA NCEI's Climate at a Glance. Cost data for recovery from incidents were used as a metric for impacts. For each state and Tribe in the region, the author team searched for the following types of documents and reviewed any that were found: heat vulnerability maps, climate action plans, hazard management plans, flood maps, and weather-relevant toolkits. The team also searched state and Tribal websites for information about responses to large storms that had recently occurred in the region. Most states and some Tribes and local governments have documented some evidence of climate planning, but the methods and types of documentation widely varied. It was rarer to find clear links to recent weather events, but comprehensive understanding of the planning process illuminates these events as motivators for climate adaptation and mitigation efforts. For example, an increase in public planning meetings and changes in funding allocations can be tracked to follow a particularly impactful storm event.

Major Uncertainties and Research Gaps

Our understanding of changes in extreme precipitation is largely based on analyses and descriptive statistics showing observed and projected changes of daily precipitation time series. Research into trends

in sub-daily and sub-hourly precipitation patterns in the region is ongoing but still inconclusive. The comprehensive body of state, local, and regional-level responses to climate change is continuously evolving and has not been summarized in any one place. This makes it difficult to quantitatively evaluate trends in climate action at different levels of government and to determine whether specific types of climate action can be generally attributed to the occurrence of specific extreme events.

Description of Confidence and Likelihood

High confidence in ongoing increases in the frequency of extreme weather, specifically precipitation, is based on both published literature analyzing daily weather trends through time and current NOAA data. These increases in extreme weather frequency were deemed *very likely* based upon evidence on precipitation and heatwaves presented in Chapter 2, with this likelihood determined to maintain consistency across chapters. The conclusion that problematic flooding is *very likely* due to extreme precipitation was determined through actual event tracking based on knowledge of storms, NOAA NCEI's database (https://www.ncdc.noaa.gov/stormevents/), and newspaper searches. Efforts to address climate change through adaptation and mitigation are also determined through web searches that show both news reports and multiple efforts that include mitigation planning. *High confidence* regarding the increase of adaptation and mitigation activities across the region, including natural and nature-based features, comes from less formal web searches, personal knowledge, and author team discussions. *Medium confidence* in the influence of extreme events on adaptation and mitigation efforts is based on the balance of evidence discovered when searching for attribution of reasons for planning and implementing these efforts.

Key Message 21.2

Ocean and Coastal Impacts Are Driving Adaptation to Climate Change

Description of Evidence Base

There has been a significant growth of peer-reviewed literature since NCA4 on climate change impacts on ocean and coastal environments in the Northeast. Ocean temperatures have increased,[291] and several marine heatwaves[65] have occurred in the region. These changes have impacted the marine ecosystem from phytoplankton to whales, with consequent effects on fisheries and the fishing community.[59] Coastal forests in some parts of the region have been affected by saltwater intrusion due to sea level rise, transforming them into tidal marshes.[122] Documentation on climate adaptation has come through formal reports and peer-reviewed literature in the field.

Major Uncertainties and Research Gaps

The responses of the coastal and marine food webs to the effects of multiple stressors (e.g., warming, marine heatwaves, loss of oxygen, and acidification) in the Northeast are currently not well understood. Additional research would help to fill knowledge gaps on the relative severity of these stressors on estuarine coastal ocean ecosystems and to evaluate the effectiveness of nature-based solutions with regard to ameliorating the impacts of sea level rise in coastal environments.

Description of Confidence and Likelihood

Confidence in the statements that the coastal ocean is warming, sea levels are rising, and ocean acidification is increasing is assessed as being *high* based on a synthesis of the published literature and formal reports. For marine heatwaves the confidence level is *high* based on peer-reviewed papers that covered limited data over a shorter time period. The statement on the existence of shifts in distribution, productivity and seasonal timing of life-cycle events of some marine species is made with *high confidence* based on

information contained in several peer-reviewed publications. For adaptation actions, the confidence level is *high* based on actions taken across state, local, and federal scales.

Key Message 21.3

Disproportionate Impacts Highlight the Importance of Equitable Policy Choices

Description of Evidence Base

Reports of statistically significant relationships among sociodemographic variables and health and well-being outcomes related to heat, flooding, and storm events are published in peer-reviewed journals.[147] There is a growing body of literature that supports the conclusion that racial and ethnic minorities and low- and moderate-income communities are disproportionately impacted by climate extremes while having less access to the resources needed to mitigate those impacts.[148,151,159] Evidence of social equity as a priority in local climate adaptation planning is provided in publicly available plans published by government agencies and nongovernment organizations.[165] Specific actions to address environmental justice challenges are provided in the plans.[172]

Major Uncertainties and Research Gaps

The complex relationships among the changing climate, sociodemographic characteristics of communities, and health and well-being outcomes are multifaceted, and no single study can capture all aspects of these relationships. Moreover, longitudinal studies are rare, but they would help capture evolving patterns of impacts and responses within individuals and to evaluate the effectiveness of communities' adaptation initiatives. There are gaps in knowledge about the equity impacts of alternative adaptation options.

Description of Confidence and Likelihood

Confidence in the statement that climate-related hazards are causing disproportionate impacts among racial and ethnic minorities and low- and moderate-income communities in the Northeast is assessed as being *very high* because it is based on the synthesis of many peer-reviewed papers and formal reports. Confidence in the statement that these disproportionately impacted communities tend to have less access to resources and face higher environmental and health burdens is assessed as being *high* because it is based on the synthesis of many peer-reviewed papers, but the relationships are hard to tease apart. The assessment of *high confidence* in the statement that social equity objectives are prominent in many local-level adaptation initiatives but that progress toward equitable outcomes remains uncertain is based on the availability of several example plans, as well as insufficient time to permit robust assessment of equity outcomes. The likelihood of observed changes and events is assessed as *very likely* based on observations of extreme weather events and official actions and the synthesis of peer-reviewed papers and formal reports.

Key Message 21.4

Climate Action Plans Are Now Being Implemented

Description of Evidence Base

The evidence base assessed for this Key Message includes formally adopted reports, plans, executive orders, and laws addressing climate risks and vulnerabilities, sources of greenhouse gas emissions, and response options from state, municipal, and Tribal governments, including the Dalal and Reidmiller (2023)[176] assessment of state-level climate actions. While state-level differences in impacts are revealed through state-specific climate impact assessments (see references in Table 21.1), broadly speaking the observed and

projected climate impacts are similar across states in the Northeast region. The state-by-state assessment of climate action revealed that most states in the region have taken ambitious, aggressive climate action through both the legislative and executive branches of government, with Pennsylvania (legislative inaction) and West Virginia (legislative and executive inaction) standing out as distinctly different. The reader is directed to Table 21.1 for a suite of state-specific resources describing climate impacts, sources of greenhouse gas emissions, and various state-government-level climate actions.

Major Uncertainties and Research Gaps

While the statements in the Key Message do not contain traditional research uncertainties, there are unknowns, including the following: Have jurisdictions adequately and comprehensively assessed their climate-related risk exposure? How much uncertainty is associated with the greenhouse gas emissions inventories that have been conducted? Are there cascading impacts or interacting stressors that are not yet accounted for? Several major unknowns will persist in any such analysis: Will the jurisdiction achieve the targets that have been set forth? What future level of warming will these jurisdictions experience? Will the anticipated impacts manifest as projected? Will jurisdictions be able to overcome nonfinancial barriers to adaptation? Will adaptation actions prove to be effective against realized impacts?

Description of Confidence and Likelihood

Confidence in most of the statements in the Key Message is assessed as being *high* because they represent an assessment of many stand-alone reports, plans, and laws. The exception to this is the final statement regarding whether mitigation targets will be met, which is assessed as having *medium confidence*, as the authors were unable to identify literature analyzing projections of emissions for each of the states in the region. Likelihood is not assessed in this Key Message because the nature of the content being assessed does not lend itself to a probabilistic assessment of the uncertainty associated with the statements.

Key Message 21.5

Implementation of Climate Plans Depends on Adequate Financing

Description of Evidence Base

Currently, the quality of the information is high and comes from reliable academic sources, federal agencies, and nongovernmental organizations. Data regarding FEMA and the National Flood Insurance Program (NFIP) are sourced directly from those entities based on the most recent data available.[280,281] However, most private risk financing and public funding information is not found in peer-reviewed literature but rather in gray literature, white papers, and case studies.[264,265] Unlike the public sector, the private sector typically does not announce adaptation work they might be financing or investing in.[264] However, the concepts behind public- and private-sector mitigation and adaptation projects are available from reliable academic and NGO sources.[263,284]

Major Uncertainties and Research Gaps

The literature searches for the draft of this chapter unfortunately did not produce any specific examples of private-sector adaptation investment in the Northeast, for the reasons stated in the previous section. Community-based catastrophe insurance is a new financial risk transfer concept. Few extant in-force examples exist, and ultimately the concept may not gain widespread use (see Bernhardt et al. 2021[263]). Similarly, climate investment intermediaries are also a new business concept but ultimately may not achieve long-term success.[265] The recent increase in federal funding through the Infrastructure Investment and Jobs Act[288] provides opportunity to pay for climate resilience projects, but the public sector's ability and willingness to repay debt financing is uncertain.

Description of Confidence and Likelihood

This section primarily discusses human financial systems and adaptation to mitigate physical climate change risk. Confidence around impacts of the flood insurance gap is *high*, based on the low market penetration of flood insurance across the Northeast (Figure 21.9) and the fact that the NFIP policies are currently capped by law at $250,000 for structural damage,[277] far below the median cost of a single-family home in 2022.[278] The confidence around demand for climate resilience investment is *high*, as numerous Northeast states have established programs to develop a project pipeline and pass voter-approved general obligation bonds to fund project implementation (Figure 21.10). Confidence around climate impacts is *high*, based on a literature search similar to that for Key Message 21.1.[13,20,23]

Introduction

Patterns of climate risk, social vulnerability, and climate adaptation in the Southeast echo centuries of human history. The region consists of highly diverse communities and landscapes, including one of the most biodiverse areas in the continental United States. The Southeast's ecosystems, stewarded for generations by Indigenous Peoples, are now in a precarious state. Centuries of political and land-use decisions have threatened the landscape and the people, with a few prospering at the expense of many. These decisions, shaped by a long history of systemic and structural racial discrimination and aggression, continue to have lasting harmful effects on the preparedness of Southeast communities for mounting climate change threats. The institutions of slavery and intergenerational ownership of individuals as property, Jim Crow segregation, and housing discrimination have resulted in many BIPOC (Black, Indigenous, and People of Color) communities living in neighborhoods that are disproportionately exposed to environmental risks and with fewer resources to address them when compared to majority White communities (Figure 32.18).[1,2,3,4,5,6,7,8,9,10,11,12,13] Furthermore, these frontline communities—those with higher exposures, greater vulnerability, and less adaptive capacity to climate change impacts—continue to face forms of discrimination that increase their vulnerability to climate risks and reduce their options for resilience (Figure 20.1).[1,14,15] These inequities are further complicated by the Southeast's population changes, economic investments, and rising tax revenues in urban and suburban areas. Wealthier communities are able to seek out external resources needed to implement innovative climate resilience and adaptation projects.[16,17] Meanwhile, smaller and more rural communities often lack the capacity to receive and spend funding, train leadership, and advocate for climate adaptation planning.[18]

With virtually no exceptions, climate change in the Southeast continues to exhibit the trends that were reported in the last National Climate Assessment (NCA).[19] We now better understand the increasing intensity of climate stressors in the Southeast, including extreme heat, extreme precipitation events, drought persistence and strength, sea level change, and tropical cyclones (Table A4.1), as well as decreases in the intensity and frequency of disruptive cold-season events like snowfall and frost days (Ch. 2).[20]

There have been notable advancements in Southeast climate change adaptation in recent years.[19] For example, adaptation plans created by Tribal Nations have contributed to those Nations' cultural continuance in a changing climate—that is, their "capacity to maintain members' cultural integrity, health, economic vitality, and political order into the future and avoid having members experience preventable harms" (KM 16.3).[21,22] Indigenous stewardship continues in the Southeast in many contemporary Indigenous "cultural landscapes," or places where Tribal members have centuries-old connections (Box 22.3). In these places, members continue cultivating cultural practices including hunting, fishing, foraging, and ceremony.[23] The increasing hazards of climate change, pollution, and threats to land and water rights–which may be underestimated by existing environmental justice analyses[24,25]–put a strain on Indigenous Peoples' sovereignty and their ability to have high levels of cultural continuance.[21,22,26]

Moreover, communities throughout the Southeast are exploring how to spur action through communicating about climate change science across both formal (classroom) and informal (outside of classrooms) learning,[27,28,29,30,31,32,33] setting clear climate goals,[34] and responding to the mounting threats and stressors that climate change presents (Figure 31.1).[35] However, there has been an equal, if not a greater, number of failures to adequately prepare the region's homeplaces, infrastructure, economy, and livelihoods for the threats of a warming climate, seen in the poorly coordinated responses to hurricanes over many years, from Hurricanes Katrina[36] to Florence[37] and Ida,[38] especially for frontline communities.[39] Moreover, uncoordinated adaptation efforts across municipal and state boundaries to address climate change may hinder the long-term efficacy of any individual project while delaying the shared goal of securing the vitality of the Southeast.

Key Message 22.1

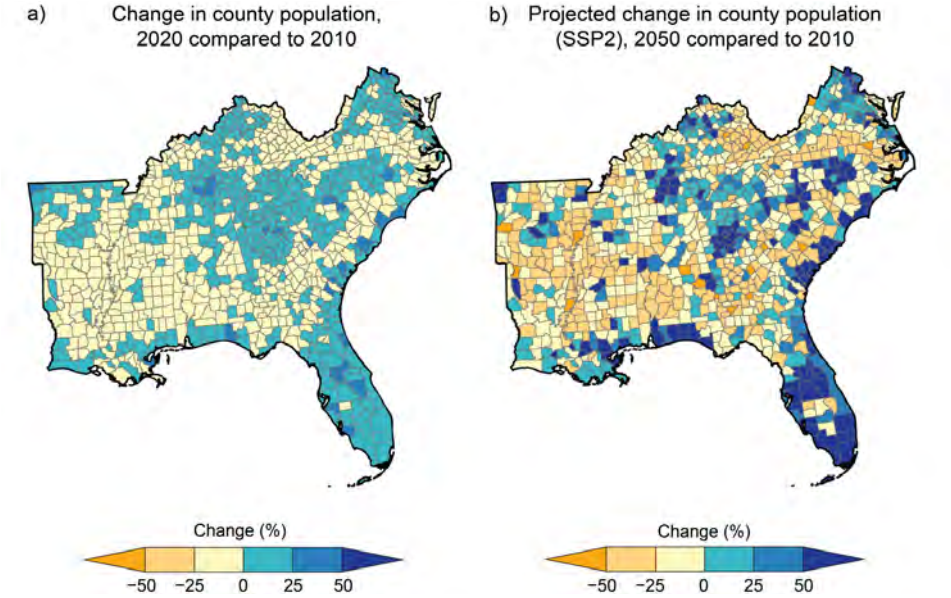
Regional Growth Increases Climate Risks

The Southeast's population has grown and is expected to continue growing, mostly in metropolitan areas and along its coastline (*very likely*, *very high confidence*), putting more communities and their assets into harm's way from increasing risks related to climate and land-use changes (*very likely*, *very high confidence*). Conversely, many rural places are facing declining populations with a growing percentage of older residents (*very high confidence*), making these areas particularly vulnerable to the impacts of a changing climate (*likely*, *high confidence*). At the same time, decision-makers frequently use outdated and/or limited information on climate-related risks to inform adaptation plans, which as a result fail to account for worsening future conditions (*likely*, *high confidence*). These climate adaptation efforts also tend to be concentrated in wealthier communities, leaving under-resourced and more rural populations, communities of color, and Tribal Nations at growing and disproportionate risk (*likely, high confidence*).

A Growing Region Means Increased Climate Risks

All but one of the Southeast's states—Mississippi—experienced population growth over the last decade, and most of the fastest-growing large US cities are located in the region.[40] Even under scenarios with moderate population growth (e.g., Shared Socioeconomic Pathway [SSP] 2), the region's population is expected to increase (Figure 22.1).[41]

Population Change in the Southeast

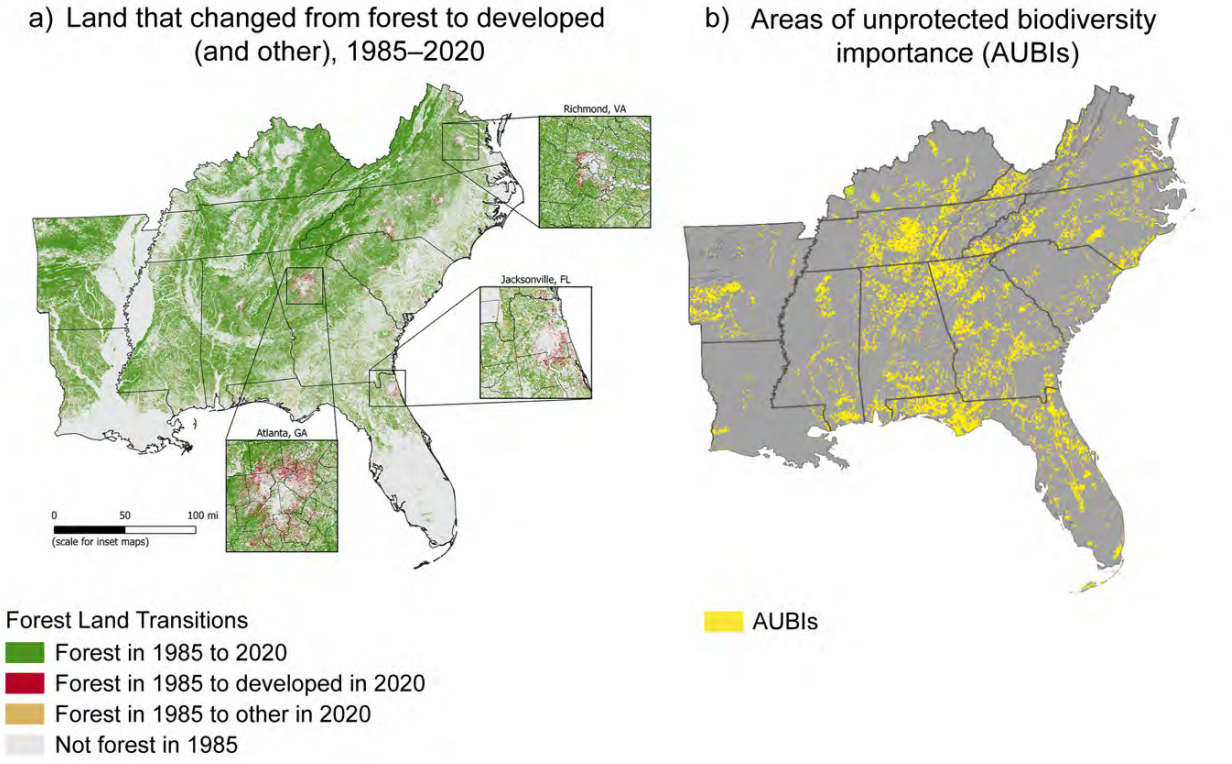


Population change in the Southeast exposes more people to climate threats along the coast and in cities while leaving rural areas with limited capacity.

Figure 22.1. (**a**) Between 2010 and 2020, unequal population change occurred in the Southeast, with coastal and metropolitan counties growing while many rural counties' populations declined. (**b**) This pattern is expected to continue through 2050 (under SSP2) and will expose more people to climate threats. Diminishing populations reduce the capacity of rural counties to adapt to climate threats by reducing critical financial and social resources, such as tax bases and community care organizations. Figure credit: Groundwork USA, NOAA NCEI, and CISESS NC.

Southeast land cover equal to about 1.7 million football fields changed from forested to developed between 1985 and 2019, more than in any other NCA region (Figure 22.2a; Ch. 6). Urbanized land cover is estimated to increase by more than 9% throughout the region by 2060, based on urban area growth trends during 1990–2010,[42] further threatening the region's unique terrestrial and aquatic biodiversity (Figure 22.2b; KM 8.1).

Land-Cover Change and Biodiversity

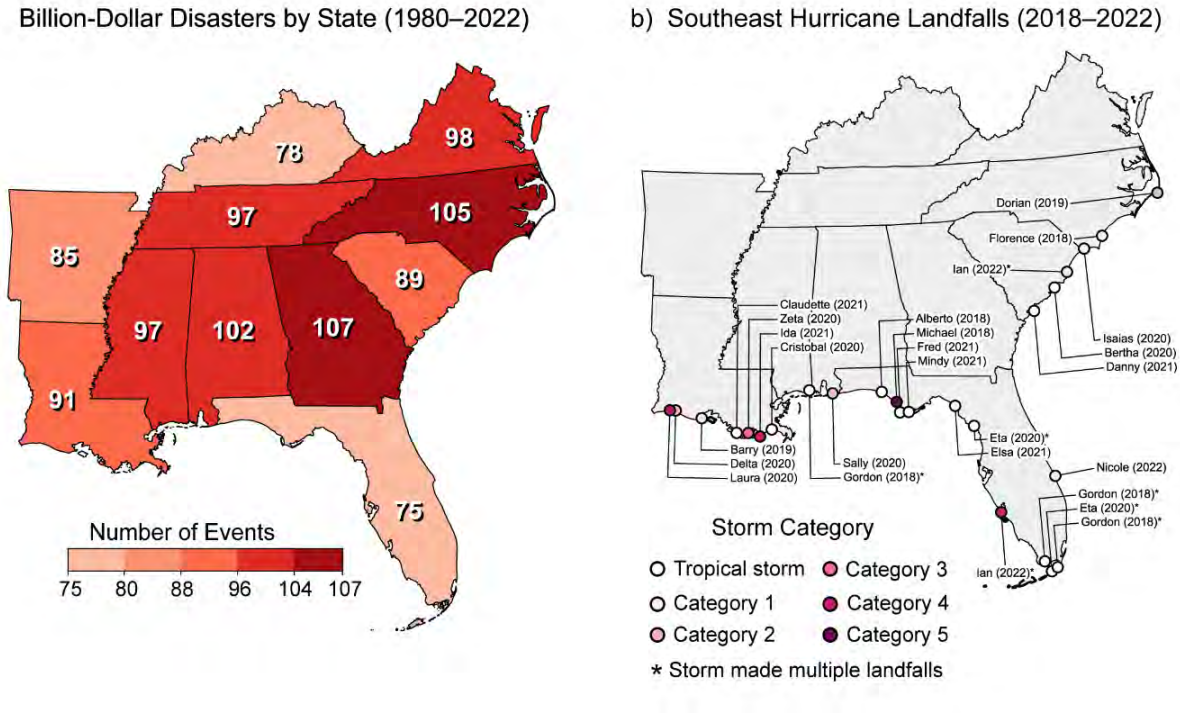


Land cover change and sprawling development threaten unprotected biodiversity hotspots in the Southeast.

Figure 22.2. (**a**) The Southeast has lost more forested area to development and other land uses (cropland, grass/shrub, and water) than any other National Climate Assessment region since 1985. (**b**) Many of the region's most biodiverse landscapes remain unprotected, threatening unique species of birds, fish, and amphibians. Future sprawl may threaten these landscapes, known as Areas of Unprotected Biodiversity Importance (AUBIs). Figure credits: (a) Groundwork USA, Oak Ridge National Laboratory, NOAA NCEI, and CISESS NC; (b) adapted with permission from Hamilton et al. 2022.[43]

Unconstrained exurban and suburban sprawl will further expose human development to weather- and climate-related risks such as wildfire,[44] hurricanes,[45] floods,[13,46] intensifying thunderstorms,[47] and tornadoes.[48] Growth along the region's coastlines[49] has increased the population exposed to coastal-specific climate threats.[13,50,51,52,53] Although the Southeast has historically experienced more billion-dollar disaster events than the rest of the country[54] and has weathered multiple hurricanes since 2018 (Figure 22.3), there is considerable regional variation among residents' perceptions of whether climate change will personally harm them.[55,56]

Billion-Dollar Disasters and Hurricanes in the Southeast



The Southeast frequently experiences costly weather-related disasters, which are worsened by climate change.

Figure 22.3. (**a**) The map shows NOAA billion-dollar disasters by state during 1980–2022 in the Southeast. The map adds up billion-dollar events for each state affected (i.e., it does not mean that each state shown suffered at least $1 billion in losses for each event). (**b**) The map shows Southeast hurricane landfalls during 2018–2022. Since 1980, the Southeast has had a higher frequency of billion-dollar disasters than other National Climate Assessment regions. Disasters attributed to hurricanes have been particularly damaging. Hurricane impacts can spread far inland and even outside the region, including major flooding, which is not captured in the Saffir–Simpson Scale depicting hurricane landfall intensity (b). Because map (b) is limited to 2018–2022, it excludes prior billion-dollar hurricanes that hit the Southeast, including Hugo (1989), Andrew (1992), Fran (1996), Floyd (1999), Charley (2004), Rita (2005), Katrina (2005), Matthew (2016), and Irma (2017). Figure credit: Mississippi State University.

Some of the Southeast's growth follows patterns of urban renewal, with affluent and young people returning to urban areas and displacing under-resourced communities to suburban and rural areas.[57] As a result of this displacement and long-standing underinvestment, under-resourced communities face more environmental hazards and increasing risks (Figure 22.4b)[3,13] but have less access to climate-ready infrastructure such as housing (Figure 22.4a), dwellings with strong building codes[58] that minimize disruption during storms,[59,60] public transit,[61] community resource centers for heat and cold relief,[62] and up-to-date stormwater management systems.[63] These communities often also lack a well-resourced local and/or state governmental workforce[64] to analyze, plan for, and mitigate risks (KM 20.1).[16,17,18,65,66]

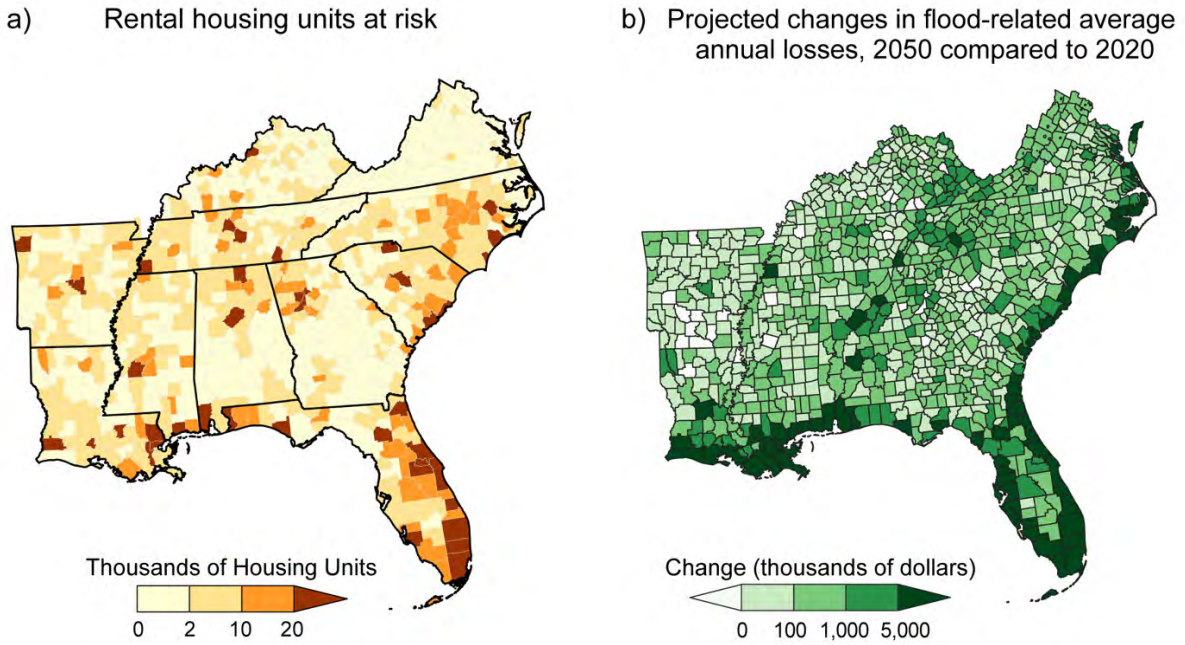
Inland and Coastal Flooding Threatens the Present and Future

Southeast flood risk is inequitably distributed due to both climate and non-climate stressors. Physical stressors such as increases in rainfall, temperatures, and sea level, in addition to land cover change, exacerbate flood risks (KM 4.2),[13,50,67,68] while social and economic policies, including institutional investments and disinvestments, differentially shape risk, vulnerability, and exposure to flooding.[69,70,71] Compounding

preexisting social and economic disparities are changes in precipitation patterns. For instance, shifting autumn precipitation patterns have been attributed to human-caused climate change,[72] and some Southeast counties with higher social vulnerability are experiencing more frequent flooding.[73]

Mandatory flood risk disclosure requirements largely depend on state-by-state policies,[74] and virtually all requirements apply only to home sales. Millions of rental housing units in the region are within counties that have high Expected Annual Loss ratings from FEMA,[75] and confidence is growing that areas currently populated by communities of color, who also are more often renters, will face disproportionately high future flood risks (Figure 22.4).[3,13] Furthermore, other forms of housing that are vulnerable to climate risks include mobile homes and manufactured housing, which are concentrated in the Southeast.[40,76,77] These populations tend to face more barriers to accessing flood insurance and federal flood disaster assistance and more often experience adverse outcomes during disaster recovery, due in part to the lack of disaster relief programs for renters and the rising cost of flood insurance.[78,79,80] Additionally, the potential overvaluation of coastal residential housing stock makes it even more challenging to move people out of harm's way due to the upper limits placed on the amount of compensation these programs can offer and peoples' reluctance to sell these properties and lose rental revenue. For example, in Miami-Dade County, Florida, the total overvaluation of properties is $3.9 billion, and in nearby Duval County, where Jacksonville is the county seat (Figure 22.5), overvaluation exceeds $420 million.[81] Across the Southeast, the average total overvaluation of properties is estimated to be around $110 million per county. Florida has the highest statewide total average overvaluation at $749 million, while Mississippi has an undervaluation of $20 million.[81]

Current and Projected Risks to Homes



Vulnerable homes in the Southeast will face increasing climate threats in the future.

Figure 22.4. (**a**) Thousands of rental housing units across the Southeast are located in counties with at least a "relatively moderate" Expected Annual Loss score in FEMA's National Risk Index. (**b**) Projected future increases to flood-related average annual losses by 2050 compared to 2020 under an intermediate scenario (RCP4.5) disproportionately affect under-resourced populations and communities of color and are amplified by population growth, exposing more people to increased flood risk. Flooding impacts infrastructure and, in turn, public health. Injury, illness, and death can result from exposure to mold from floodwater damage,[82,83] onsite wastewater treatment system failures,[84] and carbon monoxide poisoning from misuse of generators for emergency power.[85,86,87] In addition, healthcare facilities may be damaged by flooding or unable to handle an influx of demand.[88,89] Damage to roads and bridges might prevent access to these facilities, disrupt the supply of medications and equipment,[90] and hinder a community's lifeline to emergency services and evacuation routes.[91]

Tropical storms and hurricanes have been responsible for some of the Southeast's biggest and most damaging flooding events since 2018 (Figure 22.3). The likelihood of hurricanes slowing down or stalling near the coast has increased, exacerbating the rainfall-related flooding threat from these systems.[92] However, the impact of climate change on slowing down or stalling tropical storms remains uncertain,[92] although some simulations indicate a potential slowdown of Atlantic storms due to climate change,[93,94] including near the Southeast US coast.[95,96] In addition, rapidly intensifying hurricanes have presented challenges for implementing evacuations,[97] and the frequency with which Atlantic hurricanes rapidly intensify may be increasing in response to long-term human-caused climate change.[98] Also, there is evidence of increased intensification rates near the US Atlantic coast, which may continue into the future.[99] There have been significant improvements in understanding how nontropical systems,[100] atmospheric rivers,[101,102,103,104,105] past and future El Niño–Southern Oscillation patterns,[106,107] flash flooding,[73,108] and urban environments[109,110,111,112,113] add to the Southeast's risk of extreme precipitation and flooding.

With additional global warming, more North Atlantic hurricanes are expected to strengthen to at least Category 4 intensity and to undergo rapid intensification, sea level rise is expected to worsen storm surge inundation, and tropical cyclone–related rainfall is expected to increase.[93,114,115,116,117] The likelihood of storms making landfall could increase, which may offset the potential decrease in the total number of storms and overall exacerbate impacts.[118] However, some uncertainty remains regarding the expected degree of change in hurricane activity impacting the Southeast. Additionally, estimates suggest that some seasonal, annual average, and extreme precipitation amounts across the Southeast will increase, driven mainly by more extreme events (e.g., precipitation of 3 inches or more in 24 hours) at higher levels of warming.[20,67,119]

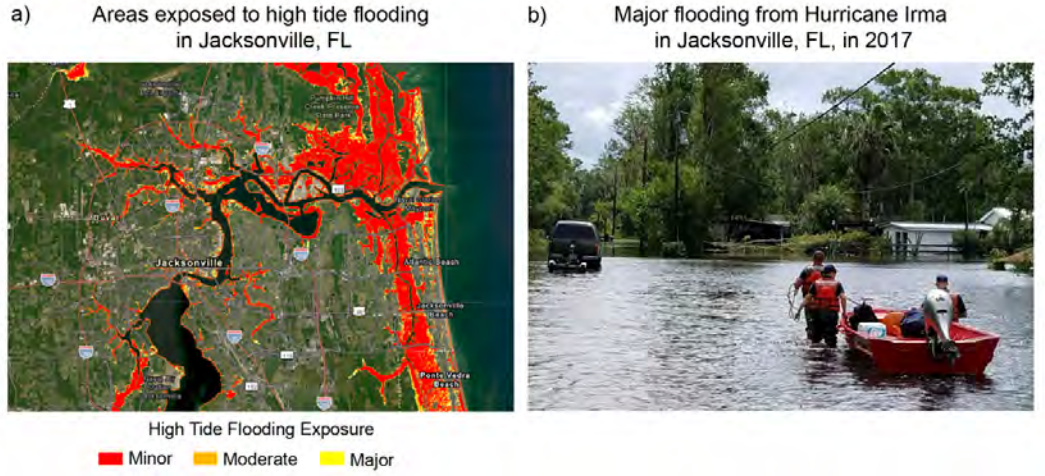
Some Southeast communities plan for these extreme events with an outdated understanding of climate-related risks.[68,120,121] Sewer infrastructure is built to accommodate a particular amount of rainfall over a specified time, and current estimates of precipitation intensity, frequency, and duration generally do not consider future projections of these metrics, posing a significant challenge to civil engineers.[122,123] Estimating future precipitation characteristics and their impact on sewer infrastructure in the Southeast is primarily conducted on a state-by-state basis and relies on different scientific approaches,[121,124] further complicating the development of design standards for climate-ready infrastructure (Figure 22.5; KM 12.2).[120]

Extreme rainfall that occurs at the same time that ocean water inundates populated areas (e.g., because of high tides or storm surges) creates compound flooding events, which can result in decreased property values[125] and roadway obstructions that can hinder first responders (KM 9.2).[66,126] Compound flooding events already affect low-lying areas in the coastal plain,[93,127] and the Intermediate-Low and Intermediate sea level rise scenarios for the Southeast project a higher frequency of compound flooding by midcentury in regions along the Atlantic coast.[128]

Tide gauges throughout the Southeast indicate that relative sea level rose by 6 inches during the 1970–2020 time period, with some variation across the region.[51] The average range of sea level rise by 2050 relative to 2000 in the Southeast (Low to High scenarios)[51] is 16–23 inches (0.40–0.58 m). This increases to a range of 2.2–7.3 feet in 2100 relative to 2000 under the same scenarios.[51] These regional estimates are higher than the projected global average rise due to regional variations in land motion, excessive groundwater pumping,[129] and the effects of sea level changes caused by changes in ocean currents.[51] For example, overall

sea level rise projections by 2050 are 22–32 inches for Grand Isle, Louisiana, 10–19 inches for Jacksonville, Florida, and 15–22 inches for Outer Banks, North Carolina. High tide flooding events in the Southeast may increase by a factor of 5–10 by 2050 due to sea level rise (Figure 22.5).[51] However, many communities will experience comparable increases in these events before 2050 due to changes in tides that exacerbate sea level rise.[52] Saltwater intrusion from rising sea levels has already degraded the health of coastal forests and estuaries while reducing their ability to store carbon,[130,131] and increased soil salinity has reduced yields in the remaining range and farmland.[132] While there is uncertainty in how global ice sheets will respond to additional global warming and thus ultimately determine longer-term sea level rise, the Southeast could experience 3.1–13.2 feet of sea level rise by 2150.[51]

Sea Level Rise and Flooding in the Southeast



Major flood events in Jacksonville, Florida, could become about 5 times more likely by 2050 under an Intermediate-High sea level rise scenario.

Figure 22.5. Sea level rise under an Intermediate-High scenario[51] would drastically increase the likelihood of flood conditions by 2050. For Jacksonville, Florida (**a**), this would mean that "minor" flood conditions (red colors) will be about 30 times more likely, "moderate" (orange colors) will be about 20 times more likely, and "major" (yellow colors) will be about 5 times more likely. This would translate to more than 250 minor floods, 10–50 moderate floods, and about 1 major flood per decade in 2050. (**b**) Major flooding impacts would resemble those experienced during Hurricane Irma in 2017, when Jacksonville experienced record-high flooding conditions. Indigenous Communities: Loss and Leadership in a Rapidly Changing Region

Indigenous communities have long faced displacement from and loss of cultural and desirable lands from settlers and government (Figure 16.1). Settler colonialism and climate change are forcing the displacement of Indigenous communities once again, causing stress and grief (KM 16.1). Indigenous communities experience substandard housing and infrastructure, as well as limited insurance coverage, which increases their vulnerability to climate stressors (KM 16.2).[134] In addition, land dispossession in the Southeast has impeded Indigenous Peoples from enduring climate hazards and deprived them of the benefits of the natural environments they once stewarded.[135,136,137,138]

Climate change and a shift from Indigenous-managed cultural landscapes to settler-managed landscapes threaten cultural knowledge and practices.[136] This shift can be seen in the loss of plants and animals of cultural significance to Southeast Indigenous communities (Figure 22.2; Box 22.3). This loss has contributed

to decreased physical and mental well-being as Tribal citizens have had to shift away from subsistence lifestyles that connect them to their cultural landscapes and contribute to cultural continuance.[22,139] Climate change also alters the ranges of native plants while enhancing the growth of invasive species that may out-compete them.[140] The loss of native species adversely affects Indigenous populations who rely on these resources for subsistence or cultural value,[141] such as coastal communities with economies driven by forests or fisheries.[142] However, Tribal Nations are finding ways to lead in responding to climate change (KM 16.3) while exercising their rights to cultural continuance and sovereignty through numerous actions and projects, including revitalizing rivercane ecosystems (Box 22.3).

Southeastern archaeological sites reveal a rich history of how Tribal Nations have met challenges similar to those they are experiencing now by using their Indigenous Knowledges.[143] However, many of these sites are exposed to the threat of rising sea level because they are located in coastal lowlands.[144] A sea level rise of approximately 3 feet (about 1 m) could result in the loss of more than 13,000 historic and prehistoric archaeological sites (with significantly more lost under more severe scenarios) while directly harming contemporary Indigenous communities across the Southeast.[144] Sea level rise also threatens coastal marshes in the Southeast more than anywhere else in the US.[145] The potential loss of these marshes, teeming with biodiversity and critical ecosystem services, could adversely affect the communities that depend on them. The ability of marshes to move (or "migrate") landward in response to sea level rise will depend on the availability of onshore land that in many cases is already developed. Planning for the migration of marshes will require a further understanding of their dynamics, as well as social trade-offs to accommodate their migration into new areas.[145]

Moving Out of Harm's Way, Protecting Existing Communities, and Planning Ahead for Growth and Potential Resettlement

The Southeast is responding to climate threats; however, these actions are spread unevenly across the region (Figure 31.1). Many communities are adopting adaptation plans, including anticipating population growth due to climate-driven relocation.[146,147,148] Tribal governments achieve greater success in developing comprehensive climate adaptation plans when joining strong cross-Tribal networks that share knowledge of effective strategies.[149] However, Southeastern adaptation plans (especially for drought and heat) are less comprehensive than those in other regions.[150,151,152,153]

Adaptation actions include avoidance, planned relocation, protection, accommodation, or some combination of these. Avoidance involves limiting development in hazardous areas. Retreat from the coast or riverine floodplains involves removing infrastructure, housing, and public facilities from hazardous areas over time while limiting future development. Protection strategies use physical infrastructure like seawalls, levees, and beach nourishment, although these may not provide long-term protection if designed for past climate conditions.[154] Accommodation involves elevating structures or using building materials that can withstand being submerged by floodwaters or are less prone to damage when exposed to fire (Figures 22.6, 22.7).

Funding needed to implement adaptation projects remains elusive for many communities, especially those with limited resources and high levels of preexisting social vulnerability.[80,155] One strategy for advancing climate adaptation is applying for FEMA Hazard Mitigation Assistance (HMA) grants.[156,157,158] However, state hazard mitigation officers who manage these grant programs have described differing levels of capacity to help local governments develop and implement HMA grants.[16] While FEMA updated its hazard mitigation planning guidance in 2022 to require that local governments and states address equity and future conditions as part of their new strategic plans,[156] the impacts of these changes have yet to be effectively assessed relative to the quality of the plans. Despite these challenges, a growing number of localities are factoring intensifying climate-related stressors into adaptation plans[35,159,160,161] and helping guide new policy (Box 22.2).

Current Tools Could Ensure Equitable Adaptation

There are several types of climate adaptation tools available to communities in the Southeast, including buyouts, information clearinghouses, land use policies, and city design and planning (Figures 22.6, 22.7).

Buyouts—acquiring hazard-prone housing that is demolished and converted to open space—are widely recognized as one of the most cost-effective strategies for reducing future losses,[162,163] including those associated with adapting to a changing climate.[164] However, while buyouts do require that the land be converted to open space after purchase, applying other proactive land-use planning techniques that guide development to safer locations or limit future growth in hazard-prone areas remains an uncommon practice.[165,166] As a result, there remains considerable uncertainty around whether communities are actually reducing risk when accounting for the losses avoided with buyouts relative to increased hazard exposure associated with new development in hazard-prone areas.[167,168,169] For example, some buyouts resulted in people relocating to an area of similar risk as their original dwelling,[170,171] and relocation in a broader context has meant moving from one risk zone to another.[172] Buyouts can also reduce a community's tax base, which can be particularly devastating in smaller jurisdictions with limited revenue to support governmental services.[173] Questions of equity in buyouts include whether buyouts are preferred by residents, whether choosing to participate in buyouts is in their best interest, and whether frontline communities are involved in deciding how and where buyouts occur (KM 20.5; Figure 20.3).[174,175,176,177,178,179] Additional buyout challenges include the long-term management of resulting open spaces, tracking buyout land in a given area, and strategies to achieve co-benefits such as creating climate-resilient recreation amenities like parks, greenways, water retention areas, and ballfields.[180,181,182] Buyout migration and relocation from one place may also exacerbate local housing pressure in another. For example, in Miami, wealthier individuals are moving from higher-flood-risk coastal areas to safer higher-elevation areas, increasing inland property values and displacing residents,[183,184,185] although the exact pressures driving gentrification and displacement within any community are complex.[186,187] There is evidence that points to the migration of some Black residents out of floodplains in the Southeast, including the case of Edgecombe County, North Carolina, where the Town of Princeville, discussed in Box 22.1, is located.[53]

A growing number of climate adaptation resource clearinghouses are available (KM 31.4), and they include Southeast case studies.[188,189] In addition, Southeast-focused organizations like the Southeast Climate Adaptation Science Center, USDA Southeast Climate Hub, and the Southeast and Caribbean Disaster Resilience Partnership provide resources needed to advance adaptation strategies, including resources for rural and/or under-resourced communities.[18,64] Some climate change planning documents even now center on additional considerations such as equity in their frameworks.[190] However, inequitable access to resources and constraints on workforce capacity to effectively use these tools can also lead to unequal progress toward implementing strategies across communities.

Climate-resilient community design principles are being employed by urban planners, landscape architects, and architects, as well as by an increasing number of municipalities (Figures 22.6, 22.7, 12.8).

Climate-Resilient Neighborhood Design

Climate-resilient community design can ensure the long-term vitality of cities.

Figure 22.6. Climate-resilient urban design may incorporate nature-based, infrastructural, and community-based solutions to alleviate the harm from climate stressors such as extreme heat and flooding. Participatory processes can foster shared ownership of climate resilience strategies and promote the distribution of resources to where they're needed most. Equitable reduction of climate risks and ensuring the reliability of critical services can create social benefits. Figure credit: Groundwork USA and North Carolina State University.

Box 22.1. Reducing Flood Risk in Princeville, North Carolina

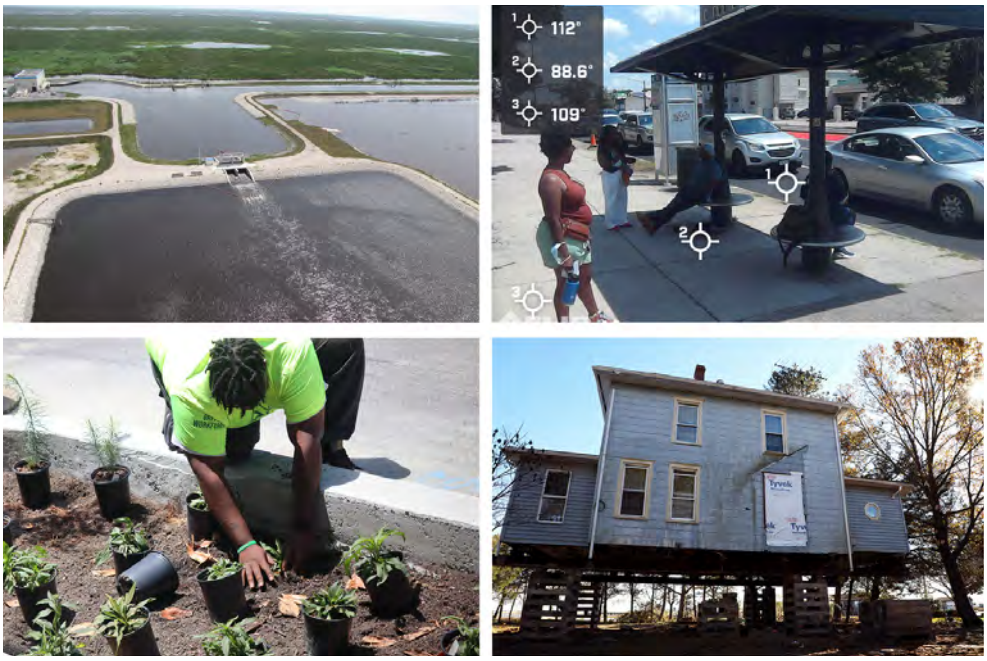
Land-use decisions dating back to the post–Civil War Reconstruction era placed Black communities in lower-lying, historically flood-prone areas across the Southeast. One example is the community of Princeville, North Carolina, located along the Tar River.[191] Princeville is the oldest incorporated independent Black community in the United States, originally settled by formerly enslaved people.[192] The town, located entirely in a floodplain, has flooded numerous times. In 1967 the US Army Corps of Engineers constructed a levee that protected Princeville until Hurricane Floyd struck in 1999 and caused widespread flood damage to the town.[192] Research suggests that repeated exposure to varied water levels over time has reduced the levee's protective capacity.[193] Although state officials offered to use buyouts to move the town to higher ground following Hurricane Floyd, residents refused due to their deep attachment to the place.[194] In 2016, Hurricane Matthew flooded Princeville again. Residents then accepted the state's offer to fund several risk-reduction measures, including buyouts, converting acquired land to open space, elevating homes, and building replacement housing in compliance with local flood standards. The state also purchased a 52-acre parcel of land adjacent to the town's borders but located outside of the 100-year floodplain where critical facilities, businesses, and new housing are to be built.[173] Princeville provides a powerful example of how existing post-disaster funding programs and policies can guide risk reduction and adaptation in the face of a changing climate. The long-term impact of these programs on the community's overall social and physical cohesion, as well as their resilience to future storms, remains an open question.

Box 22.2. Reshaping FEMA Policy to Aid Disaster Recovery in the Gullah Geechee Cultural Heritage Corridor

The Gullah Geechee Cultural Heritage Corridor is a National Heritage Area established by Congress to recognize the unique culture of the Gullah Geechee people who have traditionally resided in the coastal areas and the sea islands of North Carolina, South Carolina, Georgia, and Florida —from Pender County, North Carolina, to St. Johns County, Florida.

Communities often consist of coastal families who represent five or more generations of Gullah Geechee heritage and whose quality of life is inextricably connected to the environment and the ecosystem services it provides. Gullah Geechee residents and other coastal citizens who reside on heirs' property, or property passed down through family members by inheritance, are highly vulnerable to negative impacts associated with extreme weather events and changing climate and ocean conditions. One such impact was former federal disaster aid policies that did not recognize the uniqueness of heirs' property, where possession is authentic but documentation can be complicated. The Gullah Geechee Cultural Heritage Corridor worked with FEMA to identify policy barriers and revisions for Gullah Geechee citizens seeking disaster and recovery aid. The Corridor used its communication network to educate communities about the newly created disaster aid revisions made to support owners of heirs' property before the 2022 hurricane season. When powerful storms struck communities in South Carolina, the Corridor team reached out to families and directed FEMA representatives to areas that were hardest hit. Through its community-driven ad hoc subcommittee on natural resources and climate change, the Corridor has also used a similar grass-roots approach to understand how climate change may be experienced differently in the coastal communities of the Corridor and has worked to identify nature-based solutions that may benefit some communities.

Climate Resilience in the Southeast



Southeast communities are adapting to climate threats in a number of ways.

Figure 22.7. (**top left**) A 60,000-acre-foot stormwater reservoir in Palm Beach County, Florida, temporarily stores peak stormwater flows. (**top right**) Transit advocates in Richmond, Virginia, document the cooling efficiency of shade structures at public bus stops. (**bottom right**) Construction workers prepare to raise a home's foundation along Virginia's Eastern Shore. (**bottom left**) Rain gardens like this one can be highly place- and community-driven projects to absorb excess stormwater and improve green space, while nonprofits like Groundwork RVA build skills for a green economy. Key Message 22.2

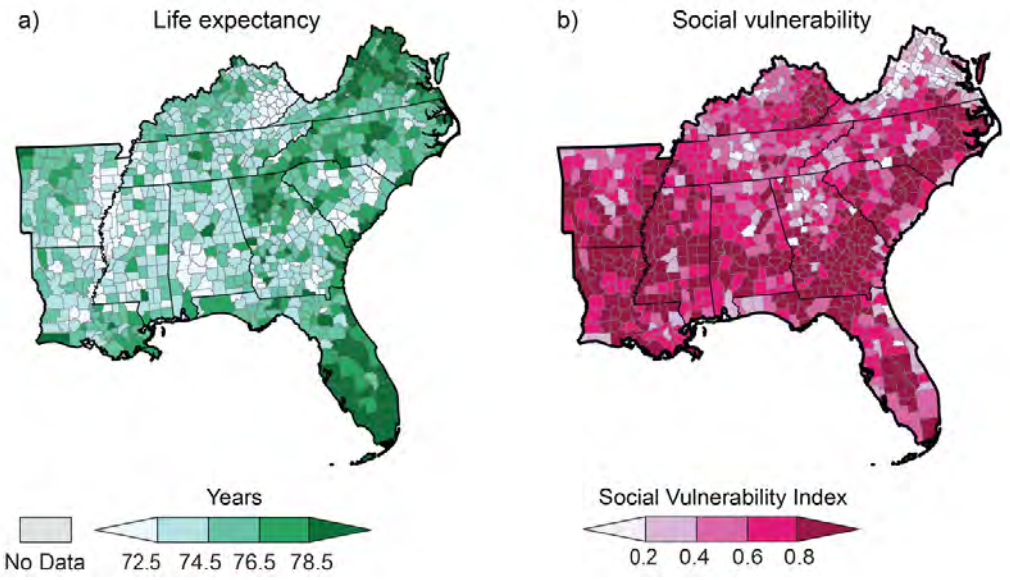
Climate Change Worsens Human Health and Widens Health Inequities

Human health and climate stressors are intimately linked in the Southeast (*very high confidence*). Community characteristics such as racial and ethnic population, chronic disease prevalence, age, and socioeconomic status can influence how climate change exacerbates, ameliorates, or introduces new health issues (*very high confidence*). Climate change is already impacting health in the region (*very likely*, *very high confidence*). There are effective strategies to address the health impacts of climate change in the Southeast that have multiple benefits across social and environmental contexts (*high confidence*).

Underlying Health Issues and History in the Southeast

Public health status is an important indicator of vulnerability to climate stressors,[190,195] and Southeasterners are consistently ranked among the unhealthiest in the Nation, with shorter life expectancies than the US average (Figure 22.8).[196] Health disparities in the Southeast are related to various social determinants of health, such as lack of access to healthcare, low socioeconomic status, and poor health behaviors (e.g., smoking and drug and alcohol abuse).[197] Sedentary lifestyles are reinforced by the quality of the surrounding built environment: the Southeast is home to 8 of the 10 least-walkable cities,[198] 15 of the 20 most dangerous cities for pedestrians,[199] and 4 of the top 10 deadliest states for cyclists in the United States.[200]

Present-Day Health Inequities



Present-day health inequities in the Southeast exacerbate climate-related risks.

Figure 22.8. (**left**) Southeastern states rank among the lowest in the Nation for life expectancy, although there is considerable variation within the region and within individual states. These patterns in life expectancy are reflected in estimates of social vulnerability (**right**)—a measure of how societal stressors like poverty, crowded housing, older populations, and lack of access to transportation may diminish a community's ability to avoid human distress and financial damages in a disaster like those made worse by climate change. Figure credits: (left) Groundwork USA, NOAA NCEI, and CISESS NC; life expectancy data from University of Wisconsin Population Health Institute, County Health Rankings & Roadmaps 2022, www.countyhealthrankings.org; (right) Science Museum of Virginia, NOAA NCEI, and CISESS NC.

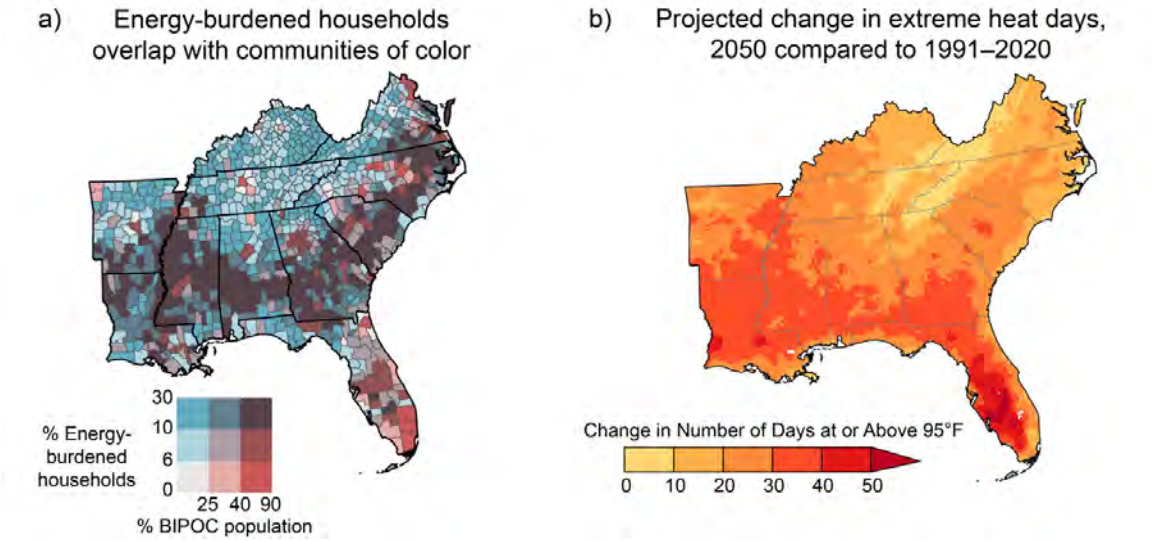
The Southeast has more Black residents than any other NCA region,[40] and health-related challenges faced by communities with majority Black populations differ from those with majority White, Hispanic, or Asian populations.[201] Communities with majority Black populations tend to have even lower life expectancies and less access to resources that promote health, such as grocery stores, safe places to exercise, and quality healthcare than whiter and wealthier populations.[202] These communities also have fewer opportunities for economic prosperity (Figure 22.12), fewer employment opportunities, limited access to quality education, and higher unemployment rates, all of which shape health outcomes.[11] Black communities in the Southeast, therefore, shoulder a disproportionate level of health risk associated with climate change.[3,12]

Keeping Cool as Temperatures Rise

Extreme heat affects everyone, but particularly at risk are pregnant people;[203,204,205] people with heart and lung conditions;[206,207] older adults and young children;[208,209] people with mental health conditions;[210,211] outdoor workers in construction, agriculture, and the service industry;[212,213] athletes;[214,215,216] and populations who lack adequate shelter or are incarcerated.[217,218]

Southeasterners rely on air-conditioning to cool living spaces, and air-conditioning demand is expected to grow across the Southeast as the climate warms.[219] However, air-conditioning prevalence varies along racial and economic lines.[220] Furthermore, the Southeast has high rates of households that experience energy insecurity.[221] While the Southeast has the lowest energy rates in the US, households there pay the country's highest energy bills.[222] High energy bills disproportionately impact rural and under-resourced residents, elderly residents on fixed incomes, and communities of color (Figure 22.9).[222] Historical *de facto* as well as *de jure* segregation policies such as redlining—the New Deal–era practice of classifying communities with significant Black, Asian, and immigrant populations as hazardous for financial investment—neighborhood housing covenants, and urban renewal have had lingering effects on frontline communities in the Southeast, resulting in their low proportion of homes that are energy efficient and affordable.[222] There is evidence that the number of blackout events (power outages) affecting more than 1,000 residents for more than one hour due to increasing energy demands and extreme weather events is increasing.[223,224,225] The Southeast has experienced many such blackout events annually and during the warm season (May–September) since 2011 (Figure 22.10).[226]

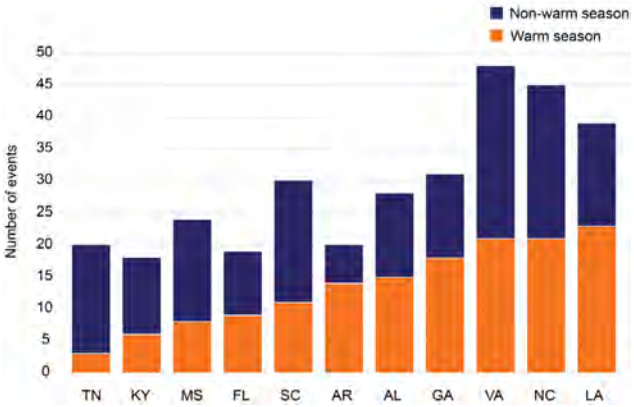
Inequitable Heat Burden and Future Heat Exposure



Projected increases in heat extremes disproportionately affect communities of color and other energy-burdened groups.

Figure 22.9. Present-day inequities will be amplified by the increased threat of extreme heat in the future. Panel (**a**) shows overlap between the percentage of the population that is BIPOC (Black, Indigenous, and People of Color) and the percentage of low- and moderate-income households with a high energy burden, or households that spend a disproportionately high amount of money on energy costs relative to their income. The dark purple areas show high overlaps between BIPOC households and high energy burden. Panel (**b**) shows the projected increase in the number of extreme heat days (maximum temperature at or above 95°F) in 2050 relative to 1991–2020 under a high scenario (SSP3-7.0). Figure credits: (a) adapted from Bryan 2020;[227] (b) NOAA NCEI and CISESS NC.

Blackouts Affecting More than 1,000 Residents for More Than 1 Hour (2011–2021)



Warm-season blackouts add to heat-related risks for residents in Southeast.

Figure 22.10. For several Southeast states, major blackout events occur most often during the warm season (May–September). Major blackouts during the warm season generally occur during heatwaves, placing people at higher risk of heat exposure and heat-related illness because they do not have access to air-conditioning. The figure shows reported major blackout events—defined as electrical grid failures affecting more than 1,000 residents for more than 1 hour—in Southeast states during 2011–2021. Data are presented as warm season (orange, May through September) and non-warm season (blue, October through April). Figure credit: Georgia Institute of Technology, Groundwork USA, CDC, NOAA NCEI, and CISESS NC.

Public cooling centers are temporary health interventions for those without adequate air-conditioned shelter on exceptionally hot days (KM 15.3). However, in some areas of the Southeast, these centers are not located within walking distance of the populations most in need.[228] Furthermore, the Southeast has the lowest public transportation access for households without a private vehicle.[229]

Heatwaves in the Southeast are happening more frequently and are occurring during a longer heat season, with some cities also showing increasing trends in their duration and intensity (Ch. 2).[3,230,231] The number of extreme warm days (above 95°F) is expected to continue increasing with every increment of global warming (Figure 22.9b; Ch. 2). Wet-bulb globe temperature (WBGT)—which measures the combined effects of temperature, humidity, wind, and sunlight on thermal comfort and which may be a better metric for the Southeast than more traditional measures of extreme heat[232,233]—has already increased due to anthropogenic climate change in parts of the region[234,235] and is expected to increase across the region throughout this century.[230,235] Additional heat stress within cities can be attributed to the urban heat island effect (Figure A4.4), whereby cities experience warmer temperatures than outlying rural areas and some neighborhoods within a city are hotter than others.[236,237] Heat island intensities across the Southeast are systematically higher in formerly redlined communities[5] and in counties with higher proportions of Black, Hispanic, and Asian residents, people with education no higher than a high school diploma, people with lower median incomes, and single-parent households.[238] However, there is a lack of consistent and appropriate thresholds used to evaluate heat risk. For example, most work-related heat illnesses across five Southeast states occurred below the heat index range designated as dangerous by the National Weather Service.[239]

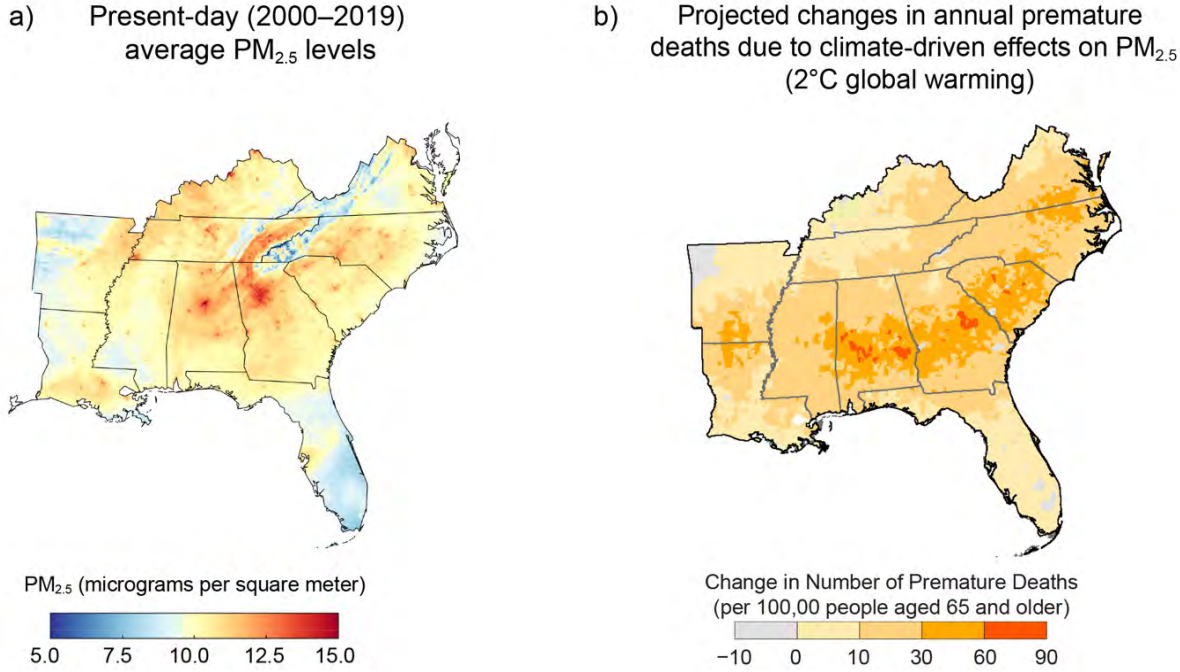
Climate change is increasing the risk of multiple dangerous weather events occurring simultaneously or in close proximity, resulting in worsened health effects (Ch. 15). An example of this is when a heatwave occurred after Hurricane Laura devastated the coast of Louisiana in 2020, resulting in at least eight deaths due to heat and an increased risk of heat-related illness, particularly for those who lost electricity and outdoor workers assisting with the recovery.[240]

In response to heat threats, Miami has institutionalized the first city heat officer to coordinate heat preparedness and response efforts to reduce impacts to the most vulnerable.

Blowing in the Wind

In the Southeast, climate change threatens Clean Air Act improvements by creating favorable conditions for increases in smog[241,242,243] and wildland fire emissions.[244,245,246] The Southeast already has significant amounts of particulate matter ($PM_{2.5}$; Figure 22.11a) as a result of anthropogenic pollutants[247] and extensive vegetation,[248] and the associated health effects are experienced disproportionately by communities of color and populations with lower socioeconomic status (Ch. 14).[249,250] Future premature deaths due to $PM_{2.5}$ in the region could be avoided through significant emissions reductions, even when considering future warming (Figure 22.11b; KM 14.3).[3,251,252] This is particularly relevant to the Southeast, which is projected to have the highest number of premature deaths due to climate-induced increases in $PM_{2.5}$ and ozone exposure.[3,251,252]

Current $PM_{2.5}$ Levels and Projected Change in Deaths Due to $PM_{2.5}$ at 2°C of Global Warming



Rising levels of air pollution from a warming climate pose profound threats to human health.

Figure 22.11. (**a**) Present-day (2000–2019) patterns of particulate matter ($PM_{2.5}$) pollution in the air are associated with excess mortality. (**b**) Potential future patterns (projected changes at 2°C of global warming relative to the 1986–2005 average) of premature deaths in people aged 65 and older due to $PM_{2.5}$ show that even when accounting for reduced particulate emissions in the future due to developments such as vehicle electrification, the Southeast is particularly sensitive to increases in $PM_{2.5}$ from increased temperature alone. (a) Adapted from van Donkelaar et al. 2019.[247] (This is an unofficial adaptation of an article that appeared in an ACS publication. ACS has not endorsed the content of this adaptation or the context of its use.) (b) Adapted from EPA 2021.[3]

In addition, airborne pollen can pose significant health risks to populations living in the southeastern United States.[253] Since 1992 in Atlanta, tree pollen concentrations have increased by approximately 4% in the spring and 10% in the fall, and weed pollen has increased by approximately 5% in the spring.[254] Some species of trees and weeds are exhibiting an earlier and longer pollen season, correlating with warmer spring temperatures.[254] Pollen increases pose significant health risks, including aggravating respiratory conditions such as asthma, which has been linked to a loss of school and work days (KM 14.4). These health risks are expected to worsen as pollen seasons shift earlier and lengthen due to climate change (KM 14.4; Figure 8.2).

Fire Danger

Wildfire risk disproportionately disrupts the lives of socioeconomically disadvantaged communities in the Southeast.[2] As more people inhabit forested areas, there is an attendant increase in wildfire risks to human health and property.[255] More hot days may also exacerbate soil moisture deficits, leading to heightened wildfire risk in the region.[244,256] Rural, mountainous portions of the Southeast are more exposed to and less equipped for mitigating wildfire.[257]

Forest managers conduct controlled, low-intensity fires, known as prescribed burns, to reduce the amount of deadwood and vegetation, thereby managing wildfire risk.[258] While the impacts of wildfires on air quality are widely recognized (KM 14.2), less is known about the impacts of prescribed burns versus wildfires on air quality.[246,259] Prescribed burns reduce the risk of wildfire damage to the environment, homes, and infrastructure, although areas with intensive prescribed burning tend to be near communities with higher social vulnerability scores, which subsequently experience more negative health outcomes from the smoke.[260,261] As conditions favorable for wildfire and unfavorable for prevention become a greater risk for southeastern communities due to a warming and drying climate,[256,262] communities may need to invest in more robust equipment and infrastructure. In 2016, wildfires in western North Carolina and eastern Tennessee highlighted the connection between exceptional drought and fire in the Appalachians.[263] Power outages and damage to PVC pipelines that supplied water to sprinkler systems led to a lack of water to combat fires, resulting in more significant damages.[264,265] That year, nearly 50% of US wildfires occurred in the Southeast, yet these fires contributed to only 29% of the total area burned that year, indicating that southeastern wildfires are smaller.[244,246,258]

Rolling Red Tides

Harmful algal blooms (HABs), also known as red tides or brown tides, occur in fresh, brackish, and salt water.[266] HABs result from the overgrowth of algae due to runoff water containing excess nutrients from agriculture and lawn maintenance, rising water temperatures, and other land-use development.[267] Since 2011, large masses of sargassum, which can fall under a HAB classification, have been increasing from Florida across the Caribbean, causing harm to coastal social–ecological systems. This problem could be intensified by rising temperatures from climate change.[268,269] HABs have significant negative impacts on human and animal health, as well as broad-reaching environmental and economic effects.[270,271,272,273]

Humans may experience various health issues from HAB exposure, such as diarrhea and headache.[273] HAB events also threaten national and local economies, as tourist areas become less desirable to visit.[271] Fisheries and aquaculture industries suffer from the loss of marine life and decreased species diversity as ecosystems are disrupted and hypoxic conditions occur,[274,275,276] and consumers are potentially exposed to seafood poisoning.[277,278] On Florida's Gulf Coast, prolonged algal events have caused a devaluation of coastal properties.[270,272]

More Than Just a Bug Bite

Temperature and precipitation changes are anticipated to shift the geographic distribution and season of certain disease-carrying mosquitoes and ticks in the Southeast (KMs 15.1, 8.2). For ticks that carry diseases such as Lyme and Rocky Mountain spotted fever, models project varying shifts in ecosystem suitability in the Southeast depending on the species, land-use changes, and host abundance.[279,280,281,282,283] Of particular concern are mosquito-borne diseases such as chikungunya, dengue, malaria, West Nile virus, and Zika virus. All have been documented in the Southeast and pose potential risks to human health.[284] Black and under-resourced neighborhoods in Chatham County, Georgia, were identified as hotspots for West Nile virus, as well as being home to communities with limited understanding of personal risk and protective measures against mosquitoes.[285,286]

The Mind–Climate Connection

The Southeast is home to 5 out of the 10 highest-ranked states for the prevalence of mental illness[287] and 8 out of the 10 lowest-ranked states for access to mental healthcare services.[288]

Climate change significantly affects mental health as a result of 1) acute disaster events such as hurricanes, floods, and wildfires (KM 15.1); 2) long-term changes such as drought[289] and heat stress;[210] and 3) existential threats of long-lasting climate change impacts that make people feel less secure in their physical environment.[290] Those who are either directly impacted by or concerned about the threat of climate change to themselves or others may experience "eco-anxiety" or "climate anxiety."[291,292]

While extreme weather events commonly occur in the Southeast, climate change has increased their frequency and magnitude (Ch. 2), causing residents to face repeated trauma and displacement at an unprecedented level, which can lead to stress and the onset of new psychiatric disorders or the worsening of preexisting mental health conditions,[293] especially among children and under-resourced and BIPOC residents.[290,294,295] The Florida Department of Health in Monroe County conducted an evaluation of its emergency shelter effectiveness in serving people with particular access and functional needs and found significant room for improvement, leading to updates to strategic planning processes and procedures related to the operation and communication of specialty emergency shelters to ensure more equitable access to shelter services.

Key Message 22.3

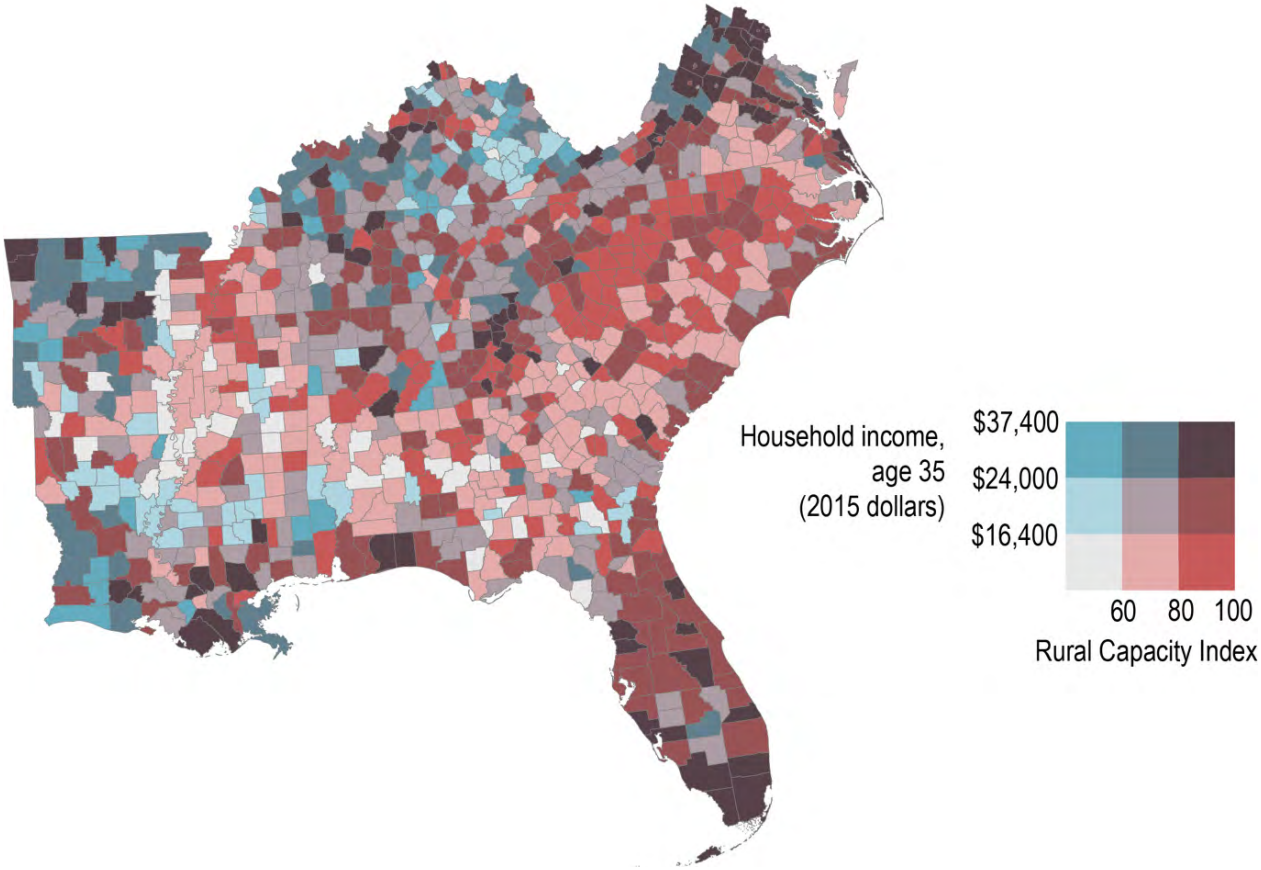
Climate Change Disproportionately Damages Southeastern Jobs, Households, and Economic Security

Over the last few decades, economic growth in the Southeast has been concentrated in and around urban centers (*high confidence*) that depend on climate-sensitive infrastructure and regional connections to thrive (*medium confidence*). Simultaneously, rural and place-based economies that rely on the region's ecosystems are particularly at risk from current and future climate changes (*very likely*, *high confidence*). Global warming is expected to worsen climate-related impacts on economic systems, labor, and regional supply chains in the Southeast, with disproportionate effects on frontline communities (*very likely*, *high confidence*). A coordinated approach that recognizes present-day inequities and the interdependencies between rural and urban communities will be necessary to secure the region's economic vitality (*very likely*, *high confidence*).

Economic Risks in the Southeast: "Less Money, More Problems"

Across the Southeast, disaster losses have increased over the last several decades, primarily due to rapid growth in hazardous areas that are driven, in part, by national, state, and local policies that incentivize development in such areas.[166,296,297] Rising disaster costs negatively impact local and regional economies, some of which are already affected by limited upward economic mobility for their population, as well as by limited administrative, institutional, and social capacity (Figure 22.12). Moreover, these multisectoral impacts are expected to worsen substantially due to climate change,[298] especially in the Southeast region (Figures 22.13, 22.14, 19.1; KM 19.1).

Household Income and Rural Capacity for Action

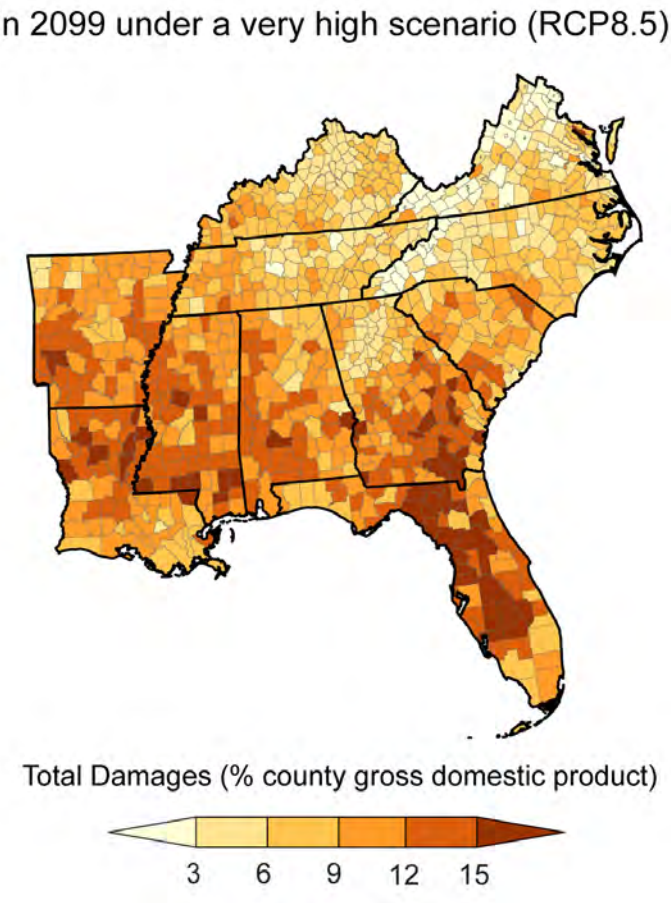


Counties where low-income households overlap with limited community capacity (shown in light gray) highlight rural climate risk challenges.

Figure 22.12. In the Southeast, children born to parents who make the lowest incomes also tend to earn low incomes as adults (blue hues), especially within frontline communities. These pockets of limited generational upward mobility may also overlap with lower scores on the Rural Capacity Index (red hues), as measured by under-resourced governance structures and limited public participation in civic processes like voting.[64] This lack of resources may leave these communities more at risk from damage due to climate change. Figure credit: EPA, Groundwork USA, NOAA NCEI, and CISESS NC.

Losses attributed to climate change are expected to increase as rapid development continues to occur in hazardous areas, particularly along coasts (Figure 22.4b),[299] while rural residents face increasing levels of isolation and economic decline (Figure 22.12).[62]

Projected Annual Economic Damages from Unmitigated Climate Change



The Southeast region faces substantial economic risks from climate change impacts.

Figure 22.13. Direct annual climate damages, as measured by the percent of county GDP, are projected to be especially large in the Southeast. The map shows damages under a very high scenario (RCP8.5) at the end of the century. Adapted from Hsiang et al. 2017.[300]

Regional Impacts of Extreme Weather Events

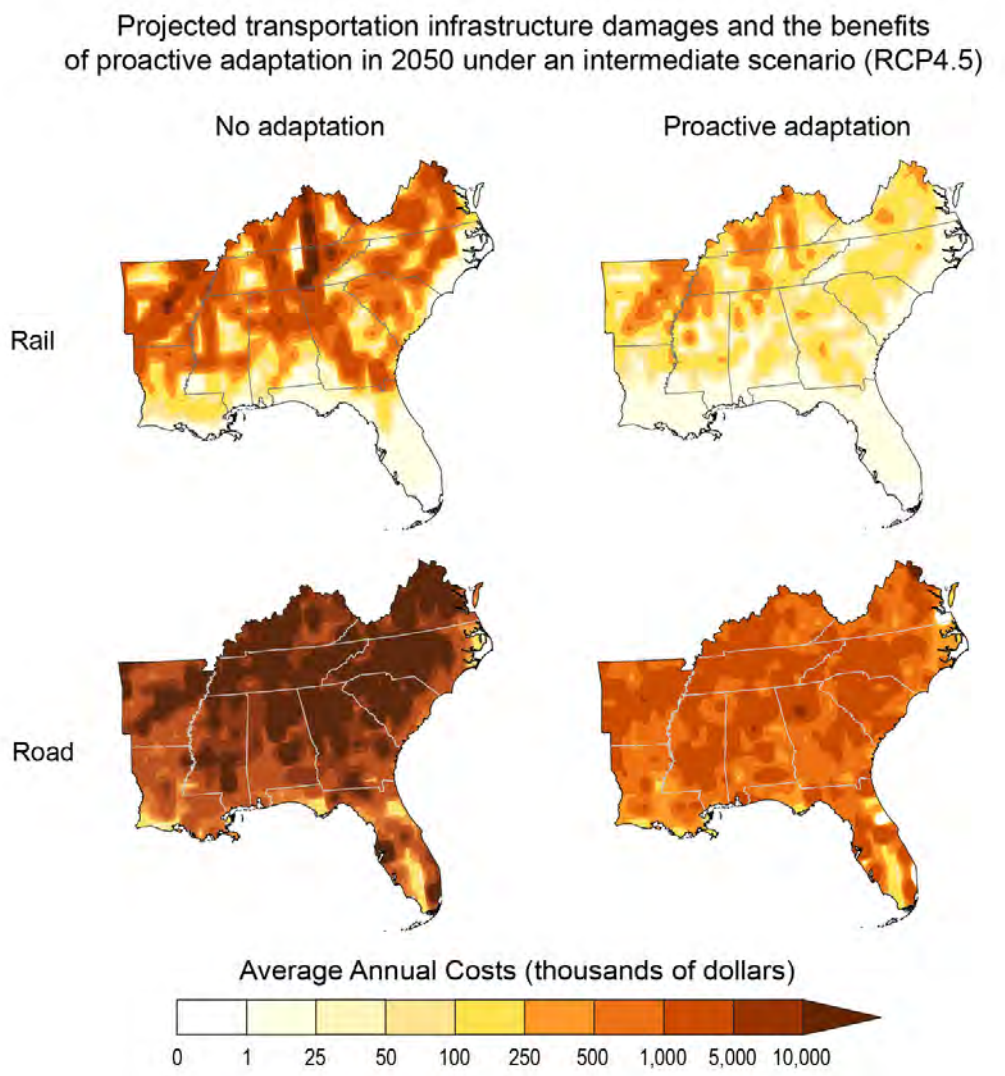
The Southeast is impacted by a wide variety of extreme weather events.

Figure 22.14. The impacts of weather and climate extremes can be seen in photos from the Southeast (**clockwise from top left**): A flooded neighborhood in Kissimmee, Florida, is shown after Hurricane Ian (2022), which heavily impacted local livelihoods. Drought conditions in Alabama (2016) directly impacted farmers' incomes and potentially increased prices for customers. Regional drought-induced low-flow conditions on the Mississippi River caused barges and towboats to become stranded for several days (2022). Flood damage in northeast Arkansas impacted transportation infrastructure and crops and may have impacted supply chains (2017). Image credits: (top left) Robert Kaufmann/FEMA, DHS; (top right) Bruce Dupree, Alabama Extension [CC0 1.0]; (bottom left) Sonny Perdue, USDA; (bottom right) adapted from NASA Earth Observatory.

Place-based economies that are located in hazardous areas and are reliant on unique ecological systems (e.g., aquaculture, farming, and recreation/tourism) face numerous challenges, including the uncertainties associated with the stability of freshwater and saltwater ecosystem services that support business and cultural attachment to place.[301] For example, some fishing communities are facing threats to fishing infrastructure due to sea level rise and more intense coastal storms, as well as threats to fisheries stock habitats that are vulnerable to the effects of a changing climate, such as increasing bottom-water temperatures.[142,302,303] Meanwhile, inland towns and cities with ecotourism attractions also face significant economic losses due to increased flash flooding,[73,108] including lower-income rural areas in Appalachia, as exemplified by the 2022 floods in eastern Kentucky. Rapidly growing urban centers in the Southeast are increasingly vulnerable to drought and the challenges tied to the provision of water for residents and businesses.[304,305,306,307] The Southeast is more drought-prone than other parts of the eastern US due to higher rates of evapotranspiration.[308,309] Evapotranspiration is expected to increase due to future climate warming (Ch. 2). Alabama cities' drought plans were evaluated as less comprehensive and lacking pre-drought preparation compared to those of California cities.[152] In rural, agriculturally dependent economies, increased heat, drought, and water-laden tropical storms currently threaten the productivity of crops and livestock (KM 22.4),[310,311] as well as the health and livelihoods of workers, who tend to be Latino migrants.[312] Future global warming will increase this threat, potentially further reducing labor productivity and costing billions

of dollars, particularly in the already hot and humid Southeast (KM 2.2).[212,313] The Southeast's economy relies on the region's ports, rivers, rail, air, and road networks, which are at risk from sea level rise, flooding, extreme heat, drought, and other climate-related hazards.[61,314] However, proactive adaptation can offset potential future climate-related damages substantially (Figures 22.13, 22.15, 22.17). Unplanned disruptions to these systems can potentially affect consumer pricing of goods, services, and livelihoods throughout the region and elsewhere (Figure 22.16).[315,316]

Proactive Adaptation Offsets Future Transportation Infrastructure Costs



Proactive adaptation to climate change could save millions of dollars in future transportation infrastructure costs.

Figure 22.15. Future climate change impacts (under RCP4.5) may cost US transportation infrastructure billions in damages by 2050, with especially high costs in the Southeast. The **left panels** show the additional annual average system costs (as compared to 1986–2005 in 2018 dollars) to rail infrastructure (**top**) and road networks (**bottom**) in 2050, assuming no adaptation. Proactive adaptation—anticipating climate risks and investing up front in strengthening these systems before damage occurs—could reduce significantly, but not eliminate, these costs (**right panels**). Proactive adaptation strategies include temperature sensors for railroad tracks and working to reduce disruption times for roads undergoing repairs. Adapted from Neumann et al. 2021[317] [CC BY 4.0].

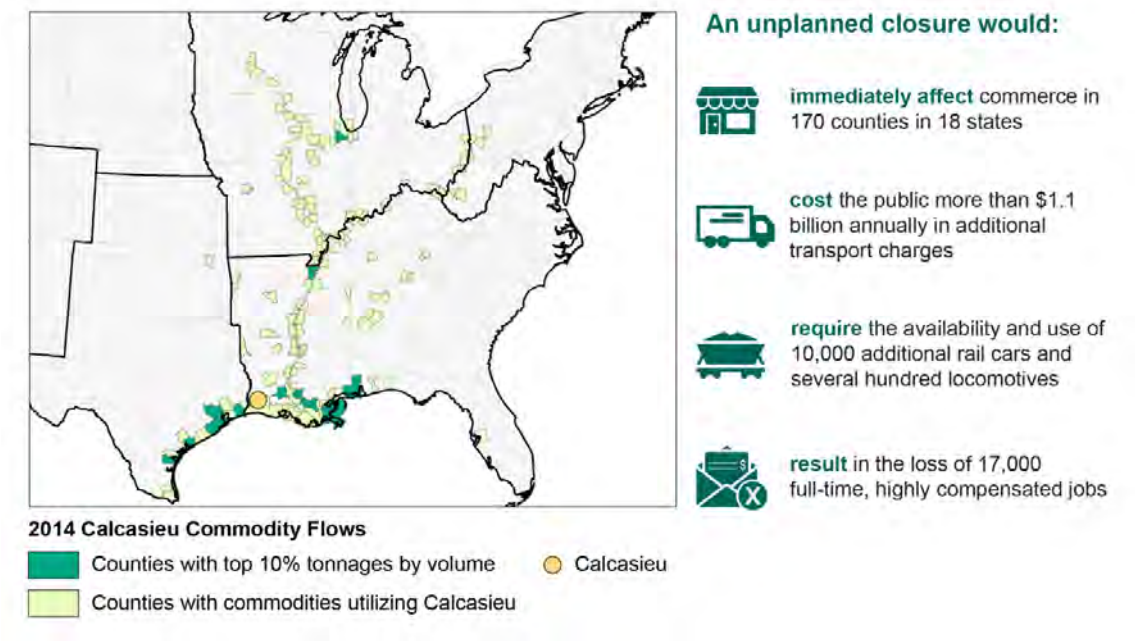
Supply Chain Impacts Affect Places Outside the Southeast

There is an urgent need to address climate change risks to global supply chains (Focus on Risks to Supply Chains; KM 19.1).[318] In the Southeast, climate change–induced transportation infrastructure risks affect all modes (e.g., air, water, highway, rail, and even pipelines; Figures 22.15, 22.16; Ch. 13). Transportation agencies across the region appear to be planning for infrastructure improvements on different schedules and often lack the capacity to include climate data in the planning process (Ch. 13).[319] Coordinated and proactive adaptation strategies could offset significant future damage to these systems (Figures 22.15, 22.17).[317,320,321]

Many Southeast roadways and rail lines are located along waterways and frequently cross bodies of water, making them vulnerable to potential floods and heat-related impacts. High future costs are expected if no adaptive investments are made today (Figures 22.15, 22.17).[317] Inland navigation and the Mississippi River are critical to supply chains in the Southeast and much of the central portion of the United States, as evidenced by the 2021 closure of the Interstate 40 bridge over the Mississippi River at Memphis, Tennessee.[322] Unscheduled lock outages resulting from floods, droughts, earthquakes, or hurricanes can cause cascading impacts. For example, an unplanned outage of the Calcasieu Lock in southern Louisiana would affect economies in 170 counties and 18 states (Figure 22.16).[315,323] In the Southeast, manufacturing facilities for industries such as automotive (including electric vehicles and charging stations),[324] solar panels, agriculture,[325] and construction often rely on parts or materials originating from other locations, including some from international sources. The Mississippi River serves as a gateway to the Nation for imports of such materials and exports of goods such as agricultural products. In recent years, low-flow conditions due to regional droughts on Southeast waterways such as the Mississippi have halted or delayed the movement of barges carrying bulk goods, with regional and national implications (Figures 22.14, 22.16).[326,327]

Disruptions can impact not only the delivery of finished goods and products to customers but also production and the livelihoods of individuals working in jobs dependent on materials from other locations that may not arrive in time, leading to revenue loss and even potential job loss if disruptions become regular and significant enough. The impacts of climate change on supply chains include not only disruption to systems and additional costs associated with the transportation of goods but also potential health impacts to workers in industries that require working outdoors, such as agriculture,[325] fisheries, construction, and last-mile delivery,[328,329] who may be exposed to extreme heat or cold. Workers in these jobs may require additional heating or cooling or adjustments in shift times to avoid exposure to adverse weather conditions (KM 22.2; Ch. 19).[330]

Expected Impacts of an Unplanned Calcasieu Navigation Lock Closure

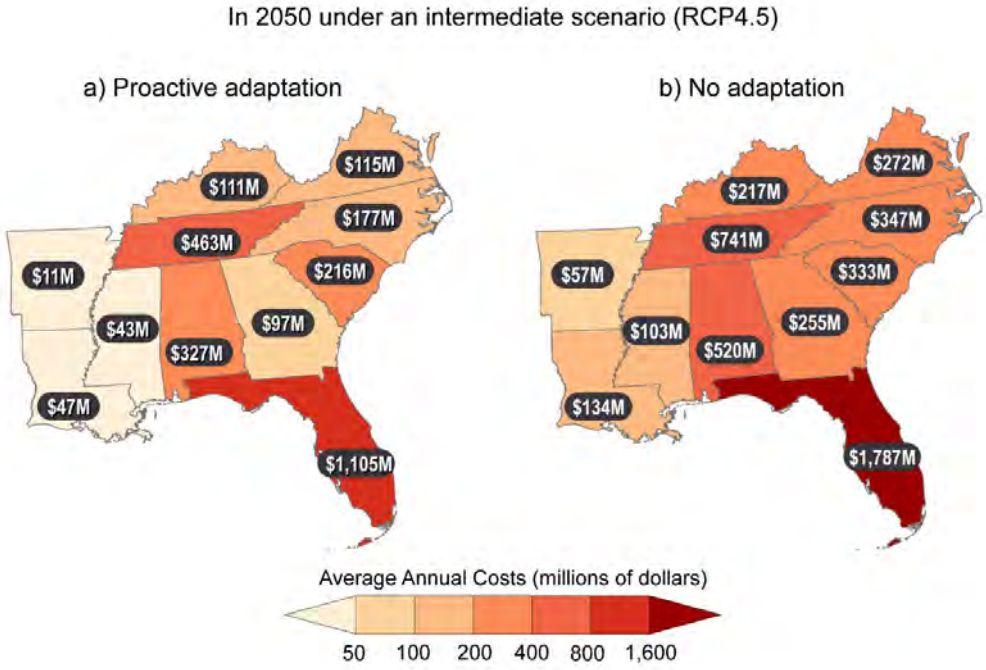


An unplanned closure of the Calcasieu Navigation Lock would have impacts that extend well beyond the Southeast.

Figure 22.16. The commodity flow impacts associated with an unplanned shutdown of Calcasieu Lock extend well outside the Southeast, affecting 170 counties across 18 states. Weather and climate extremes such as regional drought and low-flow conditions on the Mississippi River can result in unplanned shutdowns of the Calcasieu Lock. Adapted with permission from Burton et al. 2017.[315]

Furthermore, the Southeast is a hub of activity for oil refineries that provide fuel to the eastern half of the United States.[331] Climate change is expected to negatively impact not only refineries that are located along the Gulf Coast but also the distribution networks of the petroleum products that many rely on for emergency services, backup power generation, air travel, and more.[60,332,333]

Projected Annual Energy Infrastructure Costs



Proactively investing in strengthening our electrical infrastructure offsets significant future costs due to climate change damage.

Figure 22.17. The Southeast faces some of the highest economic risks related to energy infrastructure damage without proactive adaptation measures in place—such as energy utilities and policymakers' anticipating climate risks to electrical grid infrastructure and investing upfront in strengthening these systems in advance of any damages. As shown in the maps, in 2050 under an intermediate scenario (RCP4.5), proactive adaptation (**a**) could save as much as twice the total costs (in 2017 dollars) of no adaptation (**b**). These costs could be passed onto consumers. Adapted from Fant et al. 2020[320] [CC BY 4.0].

Securing Economic Vitality

Protecting businesses and urban and rural infrastructure investments may require adopting a combination of adaptation measures (KM 22.1). However, to avoid unintended disparities in service provision, these infrastructure investments should consider the needs of frontline communities in their design criteria.[334] For instance, Charleston, South Carolina, has explored questions surrounding the appropriate selection of adaptation measures, including protection techniques such as a seawall versus a greater reliance on nature-based solutions.

Justly transitioning to a low-carbon economy provides opportunities for businesses[335] as well as labor,[336] assuming that marginalized populations and women are included in this workforce to avoid the inequities of our current energy labor markets.[337] Business and governmental agencies could commit to workforce programs for employees in the oil, gas, and coal-producing industries,[336,338] as workforce training in green technology must address challenges associated with transitioning away from economies that are closely tied to a community's way of life.[339,340] Additionally, ecosystem restoration and nature-based green infrastructure solutions (e.g., urban forestry, stormwater retention gardens, green roofs) may also provide meaningful job opportunities (Ch. 19).[341] Key to adapting to climate change and leveraging new opportunities is the need for training and workforce development, which will require investment and prioritization (Ch. 19).

Key Message 22.4

Agriculture Faces Growing Threats, but Innovations Offer Help

Changes in temperature, drought, extreme rainfall, and sea levels are already threatening the Southeast's agriculture and other food-related systems (*likely*, *very high confidence*). Moreover, these climate-related hazards are expected to worsen with every increment of global warming, disproportionately harm farmers and small-scale operations, and increase the competition between urban and rural communities for valuable resources such as water and land (*high confidence*, *very likely*). However, innovative agricultural techniques such as precision farming show promise for adapting to future climate changes in the region (*likely*, *high confidence*).

Agriculture is critical to the economy of the Southeast through its production of food and fiber and employment. In the United States as a whole, agriculture, food, and related industries contributed $1.26 trillion (in 2022 dollars; a 5.2% share) to the gross domestic product in 2019.[342] In the Southeast, nearly 500,000 farms produced market sales of more than $83.8 billion (in 2022 dollars),[343] and the region's agricultural products are consumed locally and exported throughout the United States and the world.[344] Food systems distribute agricultural products throughout the region, although food deserts are present in urban and rural areas.[345] Disparities in food distribution are especially pronounced in areas with concentrations of Black, Indigenous, and under-resourced communities.[345]

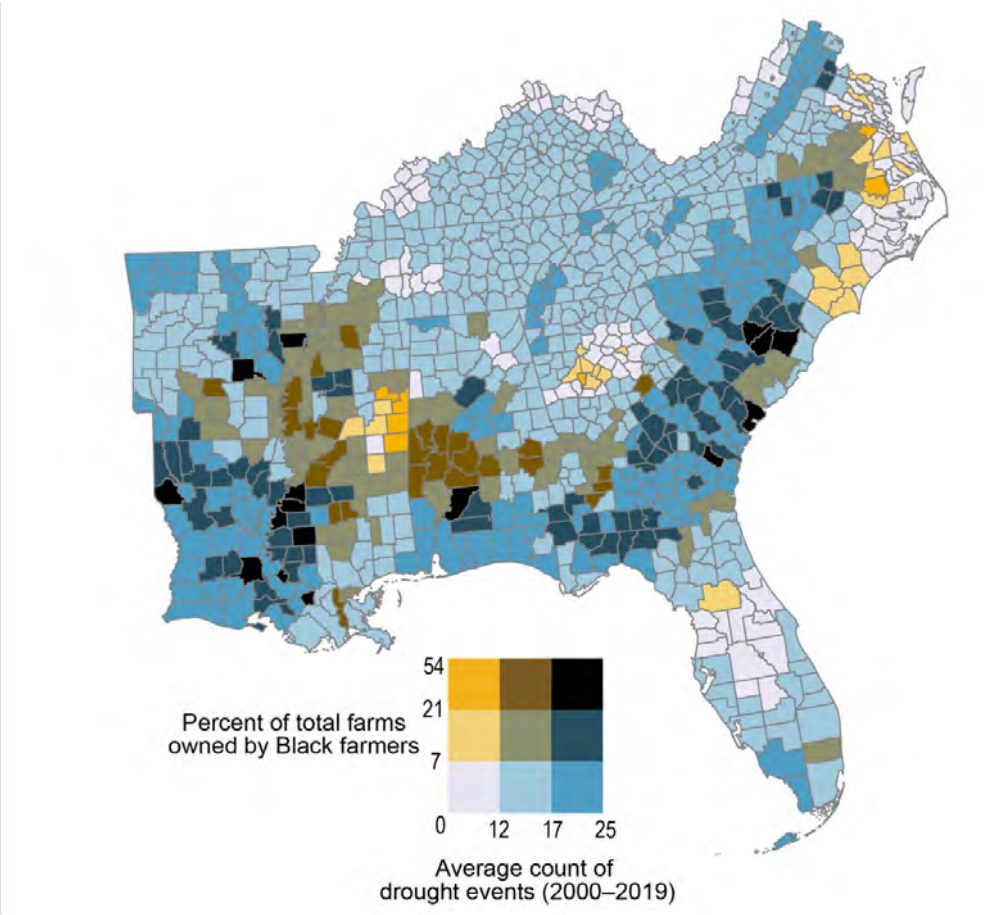
Climate Stressors on Agriculture and Food Systems

Climate change stresses agriculture and food systems (Ch. 11). Threats from a changing climate include both direct threats through impacts of climate extremes on crops, forests, ecosystems, and livestock and indirect threats through impediments to transportation, the health of outdoor workers and animals, degradation and loss of natural ecosystems, reduced productivity and loss of traditional crops, increased threats from invasive species and weeds, and loss of livelihood for vulnerable communities such as rural BIPOC farmers. For example, increased average and extreme high temperatures[346] have led to increased heat stress on livestock[325,347] and outdoor workers. Warmer winter temperatures have reduced the number of chill hours (the total number of hours a plant experiences temperatures below 45°F over the winter months), which are essential for fruit production,[348] and have caused unusually early blooming of crops such as peaches and blueberries, which makes them vulnerable to damaging frost events. In spite of warmer winters, however, the change in the average date of the last spring frost is not consistent across the region.[349]

Higher temperatures, particularly overnight temperatures, have reduced crop yields,[350] and these impacts are projected to worsen with additional global warming (Figure 22.19; Ch. 11). They have also led to an increase in the occurrence of drought in the region (Figure 22.18).[351,352,353] The Southeast is the only region in the eastern half of the United States that is prone to extreme drought,[308] and flash droughts occur with higher frequency there than in any other region.[354] Longer-term droughts in the Southeast appear to be increasing in severity but do not appear to be occurring more frequently.[355] Changes in climate conditions have also contributed to increased pressure by invasive species that have resulted in crop yield losses and damaged productive natural ecosystems.[356,357] Increases in the frequency of heavy rain events[358] and lengthening of dry spells between rain events at some locations in the region[359,360,361] make water resources unpredictable. Hurricanes and tropical storm winds, as well as increasing accumulated rainfall in coastal areas, pose unique threats to agriculture.[92,362] For example, following Hurricane Florence, swine feces markers were detected in surface waters in North Carolina, suggesting that management practices should be examined in areas at risk of increased extreme precipitation.[363] Rising sea levels have increased saltwater intrusion in coastal aquifers, reducing the extent of available forests and farmland[130,131] and threatening

seafood harvesting in estuaries by altering the salinity and turbidity in freshwater streams and marine nurseries.[364] Extreme weather and coastal stressors have also disrupted food distribution by closing ports and highways,[365,366,367] reduced the catch of fish, and diminished crop production.[140]

Droughts and Black Farmers in the Southeast



The Southeast's Black farmers face disproportionate weather and climate risks.

Figure 22.18. In the Southeast, areas with a higher number of drought events from 2000 through 2019 often overlapped with counties that are home to relatively higher proportions of Black producers, as identified in the 2017 USDA Census of Agriculture. The Southeast has the highest proportion of Black producers when compared to any other National Climate Assessment region, highlighting how disparities in climate risks require innovation and equitable adaptation, especially for those producers who have smaller operations and fewer resources to adopt new technologies. Figure credit: Groundwork USA, University of Georgia, NOAA NCEI, and CISESS NC.

Disproportionate Impacts on Under-Resourced Communities

Climate stressors such as drought have a disproportionate impact on small-scale, Black, Indigenous, and economically disadvantaged farmers, who are more concentrated in the Southeast compared to other NCA regions (Figure 22.18).[368,369,370] These groups are under-resourced, making adaptation to climate change more difficult.[371] Knowledge gaps in best practices for small-farm management complicate information-sharing among communities across the region. Access to broadband in rural areas may limit producers' ability to monitor their fields and make appropriate management decisions.[372,373] Small-farm owners also have limited financial resources, which means they have less ability to invest in necessary farm equipment, insurance,

and other risk-reduction methods such as irrigation that could mitigate climate stress and reduce farmland value losses.[374,375] Small-scale farmers and those with limited resources may find targeted USDA programs as well as innovative techniques such as organic farming and agroforestry to be well-suited to use on their smaller farms in the future.[376,377]

Competition for Resources

Southeastern agriculture and food systems are further stressed by land, water, and resource competition between urban and rural areas.[378] Competition is highlighted by decades of lawsuits in the Southeast involving the appropriate distribution of water resources among municipal water users in large cities, agricultural producers using irrigation to protect against drought, and coastal fisheries that rely on balanced salinity levels to maintain the health of estuarine systems.[379] Sprawl is expanding into farmland, reducing the land available for food production and increasing the area affected by urban heat islands.[380] Similarly, native forests have been developed or replaced by commercial forests, which may lack biodiversity and ecosystem resilience.[381]

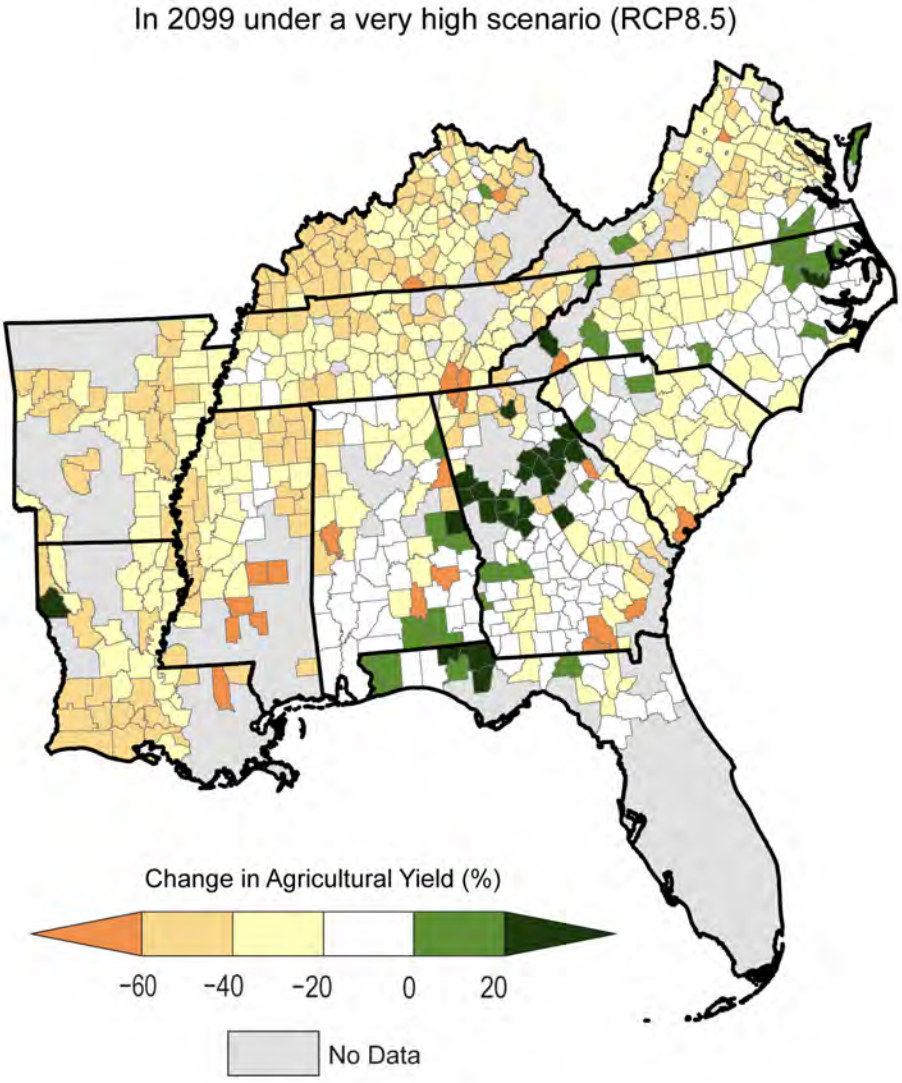
Regional Dependencies

Climate stressors in other regions can have cascading effects on the Southeast and in turn the entire United States. For example, sea level rise is expected to hinder the operation of ports where food, other agricultural products, and other needed supplies are imported and exported (KM 22.3). Additionally, low and high flows from droughts and floods may hamper the movement of food and agricultural products within and through the region, especially in highly urban and rural areas.[382,383] Climate extremes can also reduce crop yields elsewhere and thus the availability of food products for the Southeast, potentially increasing stress on under-resourced populations through cost hikes and decreasing access to nutritious food.[384,385]

How Agriculture and Food Systems Are Adapting in the Southeast

Agricultural producers are using various techniques to respond to increased climate stress, which is expected to result in decreased crop yields in many parts of the Southeast (Figure 22.19).[300] Precision agriculture can minimize water use through the timely and appropriate irrigation of crops based on growth stage and soil moisture.[386] The use of cover crops to preserve soil moisture and nutrients reduces the impacts of soil erosion and the leaching of nitrate into waterways and coastal estuaries, as well as the need for expensive inputs of fertilizer and irrigation water (Ch. 11).[387,388,389] Other innovative agricultural techniques such as organic farming, advanced grazing management, silvopasture, agroforestry, and other agroecological systems (Box 22.3) also show promise for adapting to future climate changes in the region through a reduction in emissions of greenhouse gases and increased carbon sequestration in the soil and vegetation.[376] New crops such as olives and satsuma citrus have been introduced to some areas to take advantage of the shifting plant hardiness zones and favorable market value of the crops.[390,391,392,393] Genetically modified organisms and new cultivars of perennial crops can contribute to reduced emissions of greenhouse gases through reductions in fieldwork and may reduce the need for inputs such as pesticides, as well as provide additional resilience to expected increases in temperature and drought that may threaten long-term yields.[394,395,396] A longer growing season also allows some producers to grow two crops in a year instead of one, reducing the likelihood of a weather catastrophe destroying a year's harvest in a single event.[397]

Projected Changes in Agricultural Yields Under Unmitigated Climate Change



Agricultural yields are expected to decrease under very high warming.

Figure 22.19. Agricultural yields (area-weighted average for corn, wheat, soybeans, and cotton) in the Southeast are expected to decrease due to the warmer climate in the future by 2099 under a very high scenario (RCP8.5). Some areas, however, may see yield increases due to less severe climate changes in these places, as well as limited impacts due to sea level rise and tropical storm damage. Decreases in crop yield are expected to negatively impact regional and national food supplies while threatening agricultural lifestyles and traditions. Adapted from Hsiang et al. 2017.[300]

Box 22.3. Indigenous Stewardship of Southeast Ecosystems: Rivercane

Rivercane (*Arundinaria gigantea*) is a Tribal cultural keystone species[398] and one of only three North American native bamboos. Once abundant and now critically endangered at just 2% of its original range, the species is still found throughout the Southeast.[399] Tribal Nations including the Cherokee, Chickasaw, Chitimacha, Choctaw, Houma, Koasati, and Seminole[400] value rivercane in cultural lifeways. It is used for food, textiles, basketry, medicine, weapons and hunting, and musical instruments. Many Tribal elders have a relationship with rivercane as a non-human relative.[401] Before settler colonialism, rivercane formed canebrakes, thickets of grasses that extended for miles, forming a feature from the South's deepest history.

Native peoples actively managed or tended canebrakes through consistent thinning to provide habitat and the required culms (stems) for cultural uses.[401] Canebrakes competed with European agriculture: cattle readily ate cane, particularly young shoots; pigs rooted for rhizomes,[402] killing the plant; and crops were planted where cane once thrived. Urbanization, removal of fire from the landscape as a management practice, overgrazing by cattle, and lack of public knowledge of rivercane's indigenousness have led to the plant's diminishment. The significantly reduced range of the rivercane is now further threatened by invasive species that are thriving under climate change.[403] Where it still exists, rivercane provides prime habitat for more than 50 animal species,[400] and at least six species require rivercane to complete their life cycles.[404]

Rivercane provides ecosystem benefits such as soil and water quality improvements and river and stream bank stabilization.[405] Rivercane produces seeds during rare mass fruiting events, the timing of which is unknown. For this reason, controlled reproduction has been limited and requires more research if the plant is to thrive in the future.[401] Current efforts are underway to restore rivercane, especially large swaths of canebrakes, as part of Tribal efforts to maintain sovereignty and cultural continuance.

> *I feel like we have to educate the public of Cherokee culture, foods, and artisan resources. It is not just rivercane affected by climate change, loss of habitat, and the public's lack of understanding of their cultural significance to our Tribal members, and other Tribes of the Southeast. — Mary W. Thompson, Eastern Band of Cherokee Indians*[406]

Rivercane in North America

Rivercane, a native bamboo, is culturally important to many Tribes in the Southeast.

Figure 22.20. (**left**) Rivercane grows by the French Broad River in Buncombe County, North Carolina. (**right**) Basket weaver Ramses King (Mississippi Band of Choctaw Indians) creates a "double-weave" basket (2014). The significantly reduced range of rivercane, largely due to land cover changes and agriculture, is now further threatened by invasive species that are thriving under climate change. Traceable Accounts

Process Description

Author selection for the Southeast chapter began with assessing the geographic distribution, career level, and academic expertise of the individuals listed in the Federal Register Notice nomination list. The chapter lead author (CL) then also assessed a number of other characteristics including demographics and previous experience with National Climate Assessment (NCA) chapter development. Initial invitations were sent following US Global Change Research Program (USGCRP) guidance. The CL extended multiple rounds of invitations until the final list of authors for the Zero Order Draft (ZOD) was complete in February 2022, achieving a distribution of career stages, expertise, and geographic representation. Additional authors were added after ZOD reviews from USGCRP agencies were assessed. Author team meetings were held virtually and were used primarily to gather consensus on the direction of the chapter content. In preparation for the public engagement workshops that were held in January and February 2022, the author team worked through the format of the engagement and how feedback would be gathered and summarized. The CL also gathered ZOD feedback from regionally focused organizations: the Southeast Sustainability Directors Network (January 18, 2022) and the Southeast and Caribbean Disaster Resilience Partnership (January 26, 2022), as well as a youth-focused event put on by the Youth Environmental Alliance in Higher Education (February 15, 2022).

Subsequent drafts of this report reflected changes and edits agreed upon by a simple majority of authors in response to several dozen comments and suggestions from public, National Academies, and USGCRP Agency reviews. Consensus on chapter-wide changes was usually unanimous, with very few changes needing considerable discussion. The largest changes to the chapter occurred during the drafting of the Fourth Order Draft (4OD), as this was the draft that would need to respond to a large number of public and National Academies comments. Many of the changes would be instituted during the All-Author Meeting in April 2023. Review Editor Tisha Holmes ratified that the changes satisfied all public and NASEM comments before submission of the 4OD for Technical Support Unit editorial review.

Key Message 22.1

Regional Growth Increases Climate Risks

Description of Evidence Base

Population growth and land-use change in the Southeast have been widely reported on in a variety of contexts, including in previous NCAs. This evidence has only gotten more detailed since NCA4.[19]

The relationship between global warming and increases in regional sea level trends has recently been substantially improved, allowing for highly detailed descriptions of future relative sea level and thus flood risks.[51] Other advances related to projections of future rainfall intensity, duration, and frequency tied to both nontropical[100] and tropical systems[92] have greatly improved our understanding of future changes in the Southeast, including its potential downstream impacts on frontline communities.[13,53]

A wide body of quantitative research and qualitative practice has shown that the proactive adoption of risk reduction measures can significantly reduce future losses tied to natural hazards, including those exacerbated by a changing climate.[154] Furthermore, there is widespread agreement that natural hazards and climate change is disproportionately impacting socially vulnerable populations.[3] Planning and the distribution of funding have the potential to significantly reduce hazard risk, including that associated with climate change. However, the application of land-use planning techniques varies widely, and access to external grant funding is more often obtained by wealthier communities.[16,17]

Major Uncertainties and Research Gaps

Projections of future population are based on many assumptions. Research on how future land-use change will exacerbate particular climate stressors in southeastern cities and across the region could help inform the best use of interventions and application of growth strategies. There have been limited analyses of adaptation activities in the Southeast, data inputs used, and evaluation of impacts. Downscaling global climate change models to inform geospatially targeted adaptation tools and techniques at the neighborhood and parcel scale is improving. However, the use of this downscaled information requires continued refinement to improve accuracy; in addition, better processes for sharing this information would help local officials, including low-wealth jurisdictions with limited staff and technical expertise. There still exists uncertainty regarding how future intensification of storms will impact design standards, such as determining the appropriate design standard in an era of climate change, who makes these decisions, and who pays for the additional costs. These questions apply to housing, public facilities, and infrastructure. It remains uncertain how well communities are reducing hazard risk when accounting for both individual projects (which have been captured effectively in terms of future losses avoided) and ongoing development, which includes a variety of standards, ordinances, and public investments. There is limited literature estimating sub-daily precipitation metric projections for the Southeast. The degree to which future land use and urbanization will exacerbate or overpower climate change–intensified risks at the local level, especially in frontline communities, is under-explored in the current literature.

Description of Confidence and Likelihood

Population trends from the US Census Bureau are highly reliable through time and space, and as such, we ascribe *very high confidence* to reporting their data as well as future population estimates that virtually without exception agree on continued regional growth, warranting a *very likely* assessment. Risk management and assessment literature is extremely consistent on how sprawl and development relate to natural disaster risk, earning these statements *very high confidence* and *likely* assessments. That governance structures of varying scales are using outdated and/or limited information on climate-related risks is a well-reported feature within the flooding, disaster preparedness, and urban planning literature, so we assign *high confidence* to these statements. There is overwhelming consensus that climate adaptation efforts are concentrated in wealthier, more resourced communities, and therefore we assign assessments of *high confidence* and *likely*. There is overwhelming consensus that under-resourced, older, and marginalized communities are at higher and increasing risk from present and future climate extremes, although the risk in rural areas is less fully assessed quantitatively, thus resulting in our assignment of *high confidence* and *likely*.

Key Message 22.2

Climate Change Worsens Human Health and Widens Health Inequities

Description of Evidence Base

There is strong evidence and consensus that climate change is already affecting the health and well-being of populations in the Southeast.[19] There is also strong evidence and consensus that climate-related environmental health stressors are projected to worsen.[19]

There is evidence that residents in the Southeast have poorer health in general compared to other US regions[196] and have limited access to healthcare resources.[202,288]

It is well established that there are preexisting inequities in health and healthcare access, safe and affordable housing, and access to resources to adapt to climate change, and that these inequities are associated with communities with a high proportion of under-resourced and BIPOC (Black, Indigenous, and People of Color) residents.[3,12,202,220]

The occurrence and projection of more frequent and intense extreme heat events are well documented by temperature models of the Southeast.[3,230,231] The literature assesses the disproportionate health impacts of heat on those most affected, including people who work outdoors,[212,213] student and nonstudent athletes,[214,215,216] and those who do not have adequate housing or cannot afford the energy costs of air-conditioning their homes.[218,220,222]

The literature outlines the causal pathway of how climate change is compromising air quality in the Southeast as a result of increasing favorable conditions for wildfires,[244,245,246,256,262] longer and more intense pollen seasons,[253,254,407] and increased production of smog,[241,242,243] as well as the subsequent health impacts. There is some evidence that warmer temperatures are associated with an increase in harmful algal bloom events,[267] which occur in fresh, brackish, and salt water, commonly occur in coastal areas in Florida, and can have detrimental effects on ecosystems, affecting plant, animal, and human health.[273]

The literature has established that climate change broadens the geographic distribution and season of certain disease-carrying mosquitoes and ticks, particularly in the Southeast, for tick-borne illnesses such as Lyme disease[281,282,283] and mosquito-borne illnesses such as West Nile virus and Zika virus.[284]

Mental health data have established that the Southeast ranks worst among all regions of the US in the prevalence of mental illness and access to mental health care services,[287,288] which is of particular concern as extreme weather events occur more frequently and intensely in the Southeast, causing displacement and stress.[293]

Major Uncertainties and Research Gaps

The degree to which health will be affected by climate change and climate adaptations is uncertain, due to various compounding factors that can influence health effects. There are few studies that quantify the health impacts of climate adaptation interventions in the Southeast, so there is a limited understanding of effective public health strategies for addressing climate change.

Because there is limited data on pollen and vector-borne diseases in the Southeast, it is challenging to fully understand the impacts of climate change on these disease exposures.

There is also limited quantitative data on the mental health impacts of climate change. This information tends to rely on survey data, qualitative data, and anecdotal information.

Description of Confidence and Likelihood

There is a high degree of agreement in the scientific literature that climate change will impact and is already impacting extreme temperature and precipitation events, air quality, water quality, the spread of vector-borne diseases, and the prevalence of algal blooms, all of which have an impact on the health of people in the Southeast, as evidenced by health outcome information including health impact assessments of recent events, health projections of future events, and environmental health trends in the Southeast. Based on this information, the authors assigned *very high confidence* that the changes in temperature and precipitation due to climate change, in conjunction with changes in air quality, water quality, the spread of vector-borne diseases, and the prevalence of algal blooms, will impact, and is *very likely* already impacting, the health and well-being of people in the Southeast.

It is well established that the conditions in which people live and work have an impact on health, which is understood as the social determinants of health. It is also well established by the literature and lived experience that marginalized populations will experience disproportionate health impacts, as that is seen consistently across public health and particularly in environmental health. For this reason, as well as because of the breadth of literature on the disproportionate impacts of climate change on the health of marginalized populations, the authors assigned *very high confidence* that community characteristics such as

racial and ethnic population, chronic disease prevalence, age, and socioeconomic status, can influence how climate change exacerbates, ameliorates, or introduces new health issues, widening the gap in health status.

Based on models of health impacts under varying climate scenarios, it is well-established that lower emission scenarios will result in less severe health outcomes. The literature is less established on the health benefits of climate adaptation efforts, as there is not a breadth of literature or evaluations on this topic, although from the literature that is available it is apparent that climate adaptation actions can improve health. For this reason, the authors assigned *high confidence* that climate mitigation and adaptation efforts can save lives and reduce the public health burden of climate change, particularly around reducing air pollutants and targeting already-marginalized communities, which is where the literature is more established.

Key Message 22.3

Climate Change Disproportionately Damages Southeastern Jobs, Households, and Economic Security

Description of Evidence Base

There is a rapidly growing literature presenting both qualitative and quantitative evidence that livelihoods across the Southeast are already being impacted by climate change in a variety of important ways (Ch. 19),[298] including place-based economies such as construction, tourism, and agriculture and aquaculture (e.g., fisheries are being impacted not only by significant hurricanes but also by geographical shifts among species in ocean waters),[408,409] as well as systems like transportation infrastructure[317] and electrical grid infrastructure[320] that undergird the distribution of goods and services in these places. Extreme weather-related disruptions and adverse working conditions created by climate change can affect both people and infrastructure systems that support local and regional economies by impacting the local community as well as regional and global supply chains.[326,327] References and figures included in Chapter 19 were instrumental to establishing author team consensus around key statements related to economic impacts being relatively larger in the Southeast than in other NCA regions.

Major Uncertainties and Research Gaps

Localized impacts on inland agriculture and tourism are not fully understood to date. The relocation of individuals and households away from climate-affected areas to other locations and their need to establish new livelihoods are not well understood, nor is the effectiveness of federal funding to support the construction of new settlements in less hazardous areas. The degree to which small and midsized businesses are adapting to climate change–related threats remains uncertain. The extent to which climate changes will impact large-scale agriculture is fairly well established, but the fiscal impact on small-scale family farms is not as well understood. There is limited research on the low-flow conditions and projections related to drought and its impacts on the Mississippi River and its tributaries as well as on the potential impacts to economies, despite how disruptive the events are to the regional, national, and global economy.

Description of Confidence and Likelihood

Based on the author team consensus reached through evaluating the evidence base presented in the literature as well as through direct and related experience in recent extreme weather and climate events impacting the Southeast, the authors have assigned *high confidence* to the statements surrounding the concentration of economic growth in urban centers, the climate-related risks to place-based economies that rely on ecosystems and to southeastern economies and labor, and the need for coordinated strategies

to prepare for the shocks and stressors of the future. *Medium confidence* was assigned to the evaluation of the extent to which urban centers depend on the interregional connections to more rural places and other urban centers due to limited peer-reviewed literature in this area. While there are reports and white papers on this subject from nonprofits and research think tanks that largely agree on the potential for disruptions to these systems to have impacts on both rural and urban centers, limited peer-reviewed studies seeking to isolate urban/rural dependencies in the face of climate change support at least *medium confidence*. Projections of future climate impacts in the Southeast are particularly robust in their evaluation of future heat and extreme precipitation risks; we assign *very likely* and *high confidence* to our Key Message statements that seek to link climate impacts to economic outcomes in the Southeast. Chapter 19 (Economics) was especially helpful in establishing our *very likely* and *high confidence* assessments.

Key Message 22.4

Agriculture Faces Growing Threats, but Innovations Offer Help

Description of Evidence Base

Evidence of trends in temperature, precipitation, and growing season are well documented in sources such as the NOAA National Centers for Environmental Information's Climate at a Glance Tool and in the scientific literature.[346,350] This literature base is extensive and covers individual states, the Southeast region, the United States, and the globe. Earlier concerns about temperature trends from satellite observations, which did not match surface-based observations, have largely been resolved by improved calibration of satellite measurements.

Trends in precipitation show changes in both amount and temporal and spatial distribution that are more difficult to separate out due to the nature of precipitation in the Southeast and its ties to sub-grid-scale processes like convection and tropical systems.[358,359,360,361] Evidence of trends in drought are less certain because of the combination of interacting contributions from temperature, precipitation variability, and soil characteristics, but are becoming more apparent in recent modeling efforts that are documented in the scientific literature.[351,352]

The impacts of climate variability and change on agricultural production have been well documented in the scientific literature in agricultural journals in recent years.[350,356] More work is ongoing as better methods for collecting in-field measurements are used to fine-tune the relationships between plant physiology and climate variables.

The assessment of the impacts of climate change on the health of workers and livestock, transportation pathways for agricultural production, and economic losses to both large-production farmers and small BIPOC farming communities has increased greatly in the last four years and is being reported in scientific journal articles in health, infrastructure, economic, and other social science–oriented journals.[325,347]

Many examples of agricultural producers implementing climate adaptation in farming exist, suggesting a willingness to address the impacts of a changing climate across diverse land ownerships.

Major Uncertainties and Research Gaps

There is significant uncertainty regarding the ability of crop species to keep pace with changes in climate (based on temperature and precipitation), although plant breeders have a long history of producing new hybrids that can improve responses to changing climate conditions. The ability of new crops to be productive in an altered climate is also uncertain due to concurrent changes in temperature, precipitation,

humidity, and soil characteristics, which interact with plant growth patterns. This leads to considerable uncertainty in the extent to which changes in crop choice and management can adapt to the future climate.

There is also uncertainty in the knowledge of carbon interactions between soils and crops, but numerous studies are underway to better document these interactions to improve future predictions.[376]

Since agriculture is a global endeavor, changes in market pricing and availability of inputs such as fertilizer, as well as outputs such as crop variety and yield, interact in a way that hinders the prediction of future agricultural outputs, droughts, and the economic effects of agricultural sales.[410] As a result, economic impacts on both large-scale farmers and economically disadvantaged farmers with small-scale operations are difficult to predict with *high confidence*.

Description of Confidence and Likelihood

Based on the high degree of agreement in agricultural and climate science journal articles in the scientific literature and assessments of recent events, there is *very high confidence* that the interactions of warming temperatures, precipitation changes, sea level, and drought with insect pests, invasive plants, and plant pathogens are already threatening the region's agriculture and food-related systems and will *likely* lead to decreased yields of many crops and production of other agricultural goods.[356,357] Evaluations of recent past storm events coupled with the strong agreement in related journal articles resulted in an assignment of *very high confidence* that rising sea levels and impacts from tropical storms will disrupt coastal and port activities.[325,347] Studies by social scientists published in the literature also demonstrate that small-scale BIPOC producers, as well as those who have limited financial resources, will be disproportionately affected by climate-related hazards;[366,367] on that basis, the authors have described this as *very likely* with *high confidence* in the expected impacts. Additionally, based on examples in the scientific literature of adaptations that producers are already making in response to changes in the climate, the authors assigned a level of *high confidence* that producers in the Southeast will be able to adapt to those changes using techniques such as precision agriculture, changes in crop type, and innovative management of fisheries, livestock, and ecosystems, and a likelihood level of *likely* was assigned based on less agreement in the scientific literature about the degree to which they will be able to do so.[386,390,394]

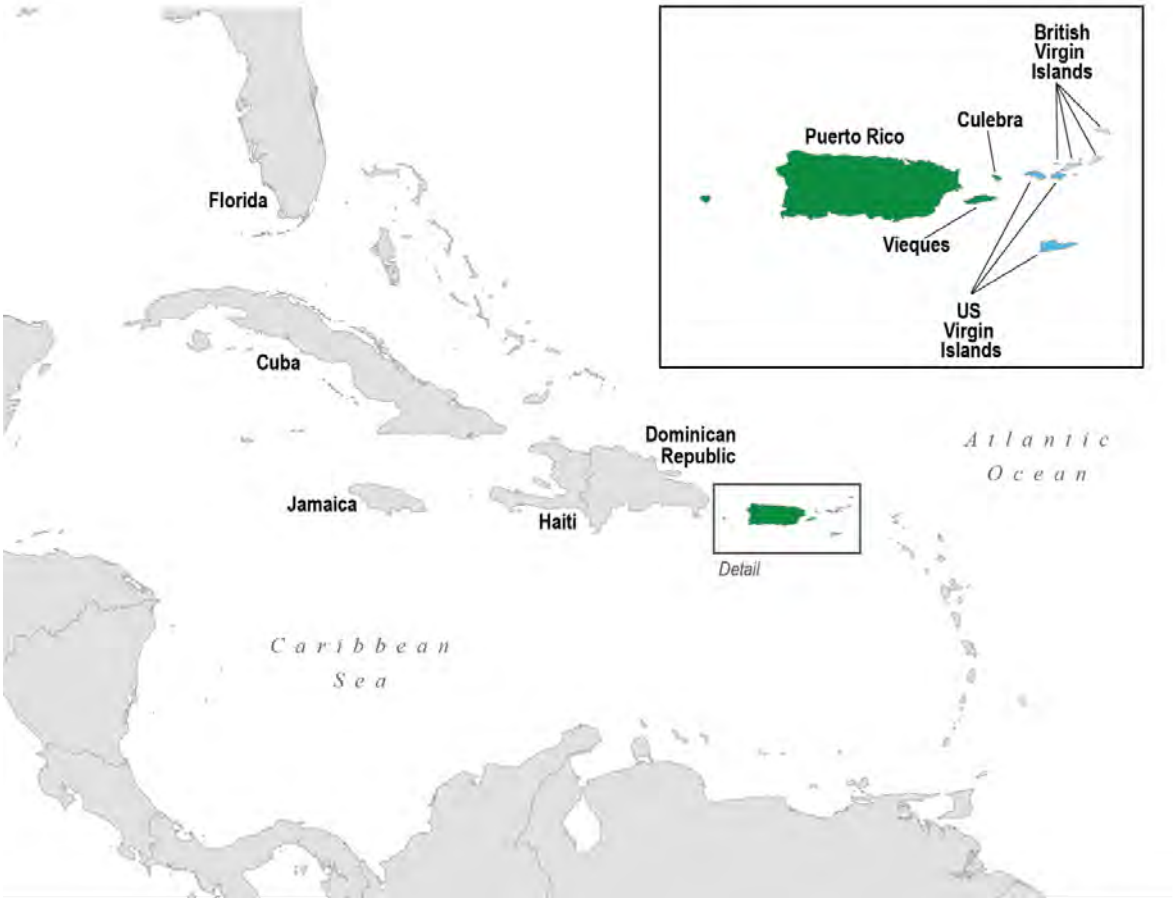
Introduction

The US Caribbean comprises Puerto Rico (PR) and the US Virgin Islands (USVI; Figure 23.1). Both are US territories, and people born there acquire US citizenship by birth. The USVI is home to about 87,000 US citizens (Table 23.1).[1] The USVI has a majority Black population and a mix of English-, Spanish-, and Creole-speaking communities. Puerto Rico (which includes the inhabited islands of Vieques and Culebra) has a population of around 3 million US citizens who are predominantly Hispanic- or Latino-Spanish speakers. Communities in both territories are now the source of significant migration to the US mainland.[2,3,4,5,6]

The US Caribbean



The US Caribbean region in the Fifth National Climate Assessment consists of Puerto Rico and the US Virgin Islands.

Figure 23.1. The map shows the location of Puerto Rico and the US Virgin Islands in the Caribbean Basin. The inset shows the main island of Puerto Rico (green; the two municipal islands of Vieques and Culebra are shown to the east and Mona Island to the west) and the US Virgin Islands (yellow; St. Thomas and St. John to the north and St. Croix to the south). Figure credit: University of Puerto Rico, NOAA NCEI, and CISESS NC.

The USVI and PR share a geographic region. Both are populated by groups that the US government considers minorities, and both face enormous socioeconomic challenges. At the same time, they have different socioeconomic, geopolitical, and climate realities. They are also quite different in scale, governance, and demographics (Table 23.1). Island residents have learned to cope with adversity due to centuries of unfavorable social inequality, colonial policies, and extreme climate events.[7]

Table 23.1. Geography of US Caribbean Territories

The sociodemographic profiles of Puerto Rico and the US Virgin Islands are grounded in long histories of colonization, systemic inequality, and parallel historical backgrounds with deeply rooted Indigenous traditions. These territories are facing similar climate-related hazards that are compounded by shrinking economies, aging populations, and ineffective government structures. Sources: Median household income from US Department of Housing and Urban Development;[8] other data from US Census Bureau.[6]

Category	Puerto Rico	US Virgin Islands
Population Living Below Poverty Level (US average: 11.4%)	43.5%	18.4%
Main Island(s) Surface Area	3,515 square miles	St. Thomas: 32 square miles St. John: 20 square miles St. Croix: 81 square miles
Total Population	3,075,000*	St. Thomas: 42,261 St. John: 3,881 St. Croix: 41,004 Total: 87,146
Principal Language	Spanish	English
Urban Population	93%	96.3%
Rural Population	7%	3.7%
Race and Ethnicity	98.7% Hispanic or Latino** (US: 18.5% Hispanic or Latino)	76% Black (Afro-Caribbean) (US: 13.4% Black or African American)
Median Household Income (in 2020 dollars; US average $67,521)	$20,539	$37,254
Population Change 2010–2020	−17.4%	−18.1%
Government	1 governor 27 senators 51 representatives 78 mayors/municipalities 1 non-voting member of the US House of Representatives	1 governor 15 senators (7 each district, 1 at-large) No representatives No mayors 1 non-voting member of the US House of Representatives

*2020 Post-Enumeration Surveys.[9] **Although "Hispanic or Latino" is the official US Census category, it does not capture the racial and ethnic diversity of PR, the Caribbean, or Latin America. The official US Census definition for "Hispanic or Latino" refers to a person of Cuban, Mexican, Puerto Rican, South or Central American, or other Spanish cultural origin regardless of race. This definition is meant to cover all Spanish-speaking cultures.

These islands are particularly vulnerable to extreme weather events that are being exacerbated by human-driven climate change, and there is increased potential for impacts because people, cities, and critical infrastructure are often located in the most vulnerable locations.[10,11,12] Extreme weather is triggering cascading, ongoing crises and highlighting political divides, which shape response and recovery efforts. At the same time, these events are revealing grassroots organizational capacities typically ignored by national- or regional-scale discourses regarding vulnerability and resilience.[13,14] A changing climate in the Caribbean highlights the interdependencies of critical infrastructure systems. In addition, climate change threatens

the preservation of heritage, particularly tangible heritage both on land and underwater.[15] In addition to catastrophic failures caused by powerful hurricanes, the impacts of extreme events in many places in the Caribbean are exacerbated by intangible factors that undermine the foundations of strong communities and functional ecosystems. Post-disaster recovery is particularly complex in the US Caribbean because of diverse cultural practices, complicated governance structures, and uneven access to information and resources, sometimes referred to as differential social vulnerability (Box 23.1).

The absence of adequate governmental response to climate change and extreme events, coupled with a long history of political marginalization, has catalyzed the rise of community-based organizations that are pursuing sustainable development efforts on their own.[13]

Box 23.1. Differential Vulnerabilities in the US Caribbean

Impacts of climate change on US Caribbean societies must be understood in the context of the social and historical processes that shape identity and exposure (see Chapter 20 for a detailed explanation of these concepts and the links to justice). Not everyone is equally impacted by climate change. Social vulnerability is a multidimensional process affected by social, political, and economic forces interacting from local to international scales.[16] In the US Caribbean, social vulnerability and social determinants of health are best viewed within a systemic risk framework and are at least partially influenced by the following:

- *Culture*: Broad ethnic diversity, different economic backgrounds, and deep historical traumas linked to colonization and struggle characterize the US Caribbean. These backgrounds shape locally relevant worldviews, risk-perception, decision-making, and adaptation and mitigation strategies. Perception of and response to climate risks include local and Traditional Ecological Knowledge and long-term memory of disasters that might or might not be transferable within or between islands (Ch. 20).
- *Access to resources*: High poverty indices and sharp social stratification, together with growing gentrification, migration, displacement, accumulated impacts from past disasters, and concerns linked to human health, influence access to resources—from economic to material objects—that could be used to lessen risks and prepare for adaptation. Aside from economic resources, access to natural resources is affected by the cumulative effects of human activities over time. In the Caribbean, for example, years of Indigenous agricultural practices, colonial plantation systems, and industrialization have contributed to reduced biodiversity, loss of forest cover, soil depletion, unstable slopes, and degraded marine ecosystems, which converge to heighten the severity of risks (Chs. 17, 18).
- *Access to information*: Climate data are often available only on scales that are too large for the needs of relatively small islands with very wide microclimatic diversity. Other barriers to accessing information include language (Spanish and English are the principal languages of PR and the USVI, respectively), educational barriers, poverty, growing indices of illiteracy, and distrust in official entities.
- *Governance*: The political relationship between the US Caribbean territories and the Federal Government affects the ability and capacity for local action. Other formal and informal systems of local governance also affect action, including grassroots leadership, local nongovernmental organizations, and religious organizations.
- *Puerto Rico's fiscal and economic situation:* The prolonged and deep contraction of Puerto Rico's economy since 2006, coupled with the fiscal crisis and the Puerto Rico government's bankruptcy, resulted in significant cutbacks in government institutions, social services, and infrastructure improvements and maintenance.[17,18,19] Such austerity measures, intensified by the escalating intervention of the federally controlled Fiscal Management Board, influence Puerto Rico's ability to address the underlying causes of vulnerability and hinder its capacity to recover and adapt.[20]

Observed and Projected Climate Change for the US Caribbean

The assessment of observed and projected climate-related trends provides information for evaluating climatic and environmental consequences of future climate changes, risks, and impacts. The following assessment builds on the most recent findings.[1,12,20,21,22,23,24,25]

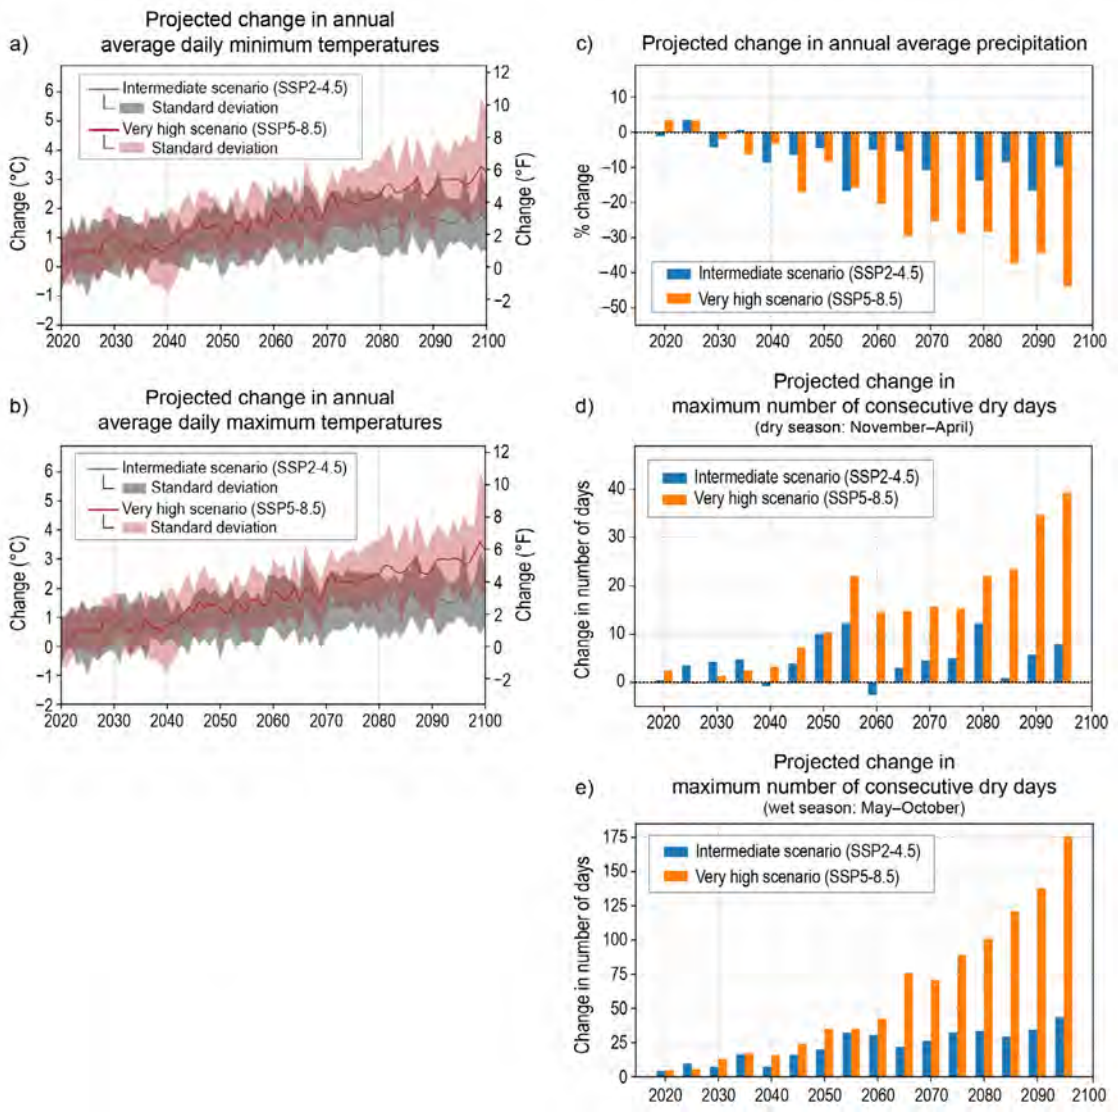
- Natural climate variability (Table 23.2), including the El Niño–Southern Oscillation (ENSO), North Atlantic Oscillation (NAO), and Saharan dust events, has an important role in the subseasonal to interannual (year-to-year) climate within the US Caribbean.
- Daily average temperatures in PR have increased by 2°F since 1950. Minimum temperatures are increasing faster than daily average temperatures, with the largest increase for minimum temperatures at lower elevations. Projections for end-of-century temperatures show additional warming, from as low as 1.1°F under an intermediate scenario (SSP2-4.5) to as high as 7°F under a very high scenario (SSP5-8.5; Figure 23.2).
- No clear long-term trend is detected in seasonal or annual average rainfall over PR, although Figure 2.4 does show a small increase (less than 5%) in Puerto Rico in 2002–2021 compared to the 1901–1960 average. However, climate models project a significant reduction in annual average rainfall by end-century with reductions of 10% for SSP2-4.5 and 33% for SSP5-8.5. The rainfall reductions for SSP5-8.5 compared to SSP2-4.5 become increasingly larger after midcentury. The consequence of reductions in annual average rainfall is a large increase in the number of consecutive dry days, especially for the wet season (Figure 23.2).
- Within the Atlantic basin, the tropical cyclone rain rate is projected to increase by about 15% and the average storm wind intensity around 3% for a global average temperature increase of 3.6°F (2°C) above present-day levels. The number of intense tropical cyclones (Categories 4 and 5) are projected to increase as well (KM 2.2). There is some indication within Puerto Rico that tropical cyclone rainfall rates are increasing over the climatological record, increasing the likelihood of extreme events like Hurricane Maria's rainfall. Sea surface temperatures have warmed, and oceans are becoming more acidic, absorbing increased concentrations of atmospheric carbon dioxide (CO_2).
- Sea level is rising and is expected to continue to rise for centuries (KM 9.1). Long-range sea level scenarios indicate an additional rise of approximately 0.6 feet (0.2 m; Low scenario) to 1.4 feet (0.4 m; High scenario) by 2050 and 1.9 feet (0.4 m; Low scenario) to 6.8 feet (2.1 m; High scenario) by 2100;[25] for connections to Shared Socioeconomic Pathways [SSPs], see the Guide to the Report). The trajectory from tide-gauge observations from within the US Caribbean archipelago from 1970–2020 aligns with the Intermediate scenario out to 2050.

Table 23.2. Large-Scale Circulation and Climate Variability

Changes in the global (large-scale) circulation affect climate variability in the US Caribbean. El Niño–Southern Oscillation (ENSO) is the strongest source of year-to-year climate variability across the globe. An ENSO warm phase is referred to as El Niño and is associated with the warmer water in the eastern equatorial Pacific. The cool phase is referred to as La Niña and is associated with cooler water in that region. These warmer and cooler waters affect the atmosphere and worldwide weather patterns. The different phases of ENSO typically last between 6 and 18 months and recur every 2 to 7 years.[26,27,28] The North Atlantic Oscillation (NAO) is an oscillation in the sea level pressure between the Icelandic Low and North Atlantic Subtropical High.[29,30,31,32] A positive NAO occurs when both the Icelandic low and the Azores high are stronger than average, which creates strong atmospheric pressure differences within the North Atlantic. A negative NAO is associated with a weak Icelandic low and Azores high and weakened pressure differences within the North Atlantic. Saharan dust (consisting of particles containing minerals, organic matter, marine salts, viruses and bacteria, quartz, calcite, hematite, sulfates, and other materials) reaches the Americas from Africa (mainly from the Sahara and the Sahel). Dust season in the Caribbean occurs between May and September (summer), with maximum peaks from June to August.[31,32]

Climate Variability	El Niño	La Niña	North Atlantic Oscillation (positive)	North Atlantic Oscillation (negative)	Saharan Dust
North Atlantic Tropical Cyclone Activity	Suppress activity	Increase activity	Suppress activity	Increase activity	Suppress activity
US Caribbean Rainfall	Weak to negligible impact	Weak to negligible impact	Suppress rainfall	Increase rainfall	Suppress rainfall

Temperature and Rainfall in Puerto Rico



Puerto Rico is projected to become warmer and drier, with increasing uncertainty in the magnitude of change beyond midcentury; just how warm and dry depends on the scenario followed.

Figure 23.2. Projected temperature and precipitation changes for Puerto Rico are shown for an intermediate scenario (SSP2-4.5) and a very high scenario (SSP5-8.5) to demonstrate the range of plausible future changes in the climate. Climate change projections are shown for annual average daily minimum (**a**) and maximum (**b**) temperatures, annual average precipitation (**c**), and maximum number of consecutive dry days during the dry season (**d**) and wet season (**e**). Both scenarios indicate a warmer and drier climate for Puerto Rico, but the magnitude of change for the very high scenario is alarming, especially when considering the availability of fresh water. The average maximum temperature increases for the end of the century (2071–2100) range from 2.8°F (1.5° C) for the intermediate scenario to 4.8°F (2.7° C) for the very high scenario. The increased temperatures, coupled with reductions in annual average precipitation at the end of the century of approximately 10% (intermediate scenario) to greater than 30% (very high scenario), are both indications of a significantly drier climate, with very large impacts anticipated for the very high scenario. A particular concern is the precipitation reduction during the wet season and the large increase in the number of consecutive days without rain, exceeding an increase of 115 days, on average, by the end of the century for the very high scenario. The bar plots in panels (c–e) are averages over five-year periods. All plots are differences relative to the entire period (2021–2100). Figure credit: NOAA NCEI and CISESS NC.

Box 23.2. Missing Data in the US Caribbean and the Pacific Islands

The US Caribbean and Pacific Islands continue to face similar challenges related to climate change (Ch. 30), including geographic constraints (e.g., limited land area, variable topography), reliance on imports, critical dependence on local natural resources (fresh water, fisheries), and differential vulnerabilities to drought, sea level rise, and natural disasters. These territories are home to underserved and underrepresented communities that are systemically excluded from data collection efforts due to administrative structures that are rooted in colonialism.[33,34] These structures, combined with the lack of data, have resulted in capacity issues that continue to promote discrimination, inequity, and inequality in a wide range of sectors (e.g., health, natural resources, education, agriculture, food security, imports, and housing).[35,36,37,38]

Data for the US Caribbean are missing for metrics such as carbon dioxide sources and carbon sinks, municipality-level population projections, and locally relevant downscaled projections for both the changes in average conditions (e.g., temperature, precipitation) and extreme events (e.g., heatwaves, hurricanes, droughts, marine heatwaves, winter storms, dust storms). Even in cases where downscaled data are available for the US Caribbean region, they are not at a fine-enough resolution to distinguish small islands such as the US Virgin Islands, Culebra, and Vieques. Furthermore, Caribbean Traditional Knowledge systems and stewardship have been foundational in responding to climate change, but generations of knowledge have been undervalued, suppressed, and ignored by Western science and have only recently been recognized as valid knowledge sources at the federal level.[39,40] By identifying and addressing the underlying causes for missing information in the US Caribbean, scientific institutions will be able to more equitably develop future research and climate assessments. Doing so would better serve evidence-based decision-making throughout the Caribbean region.

Key Message 23.1

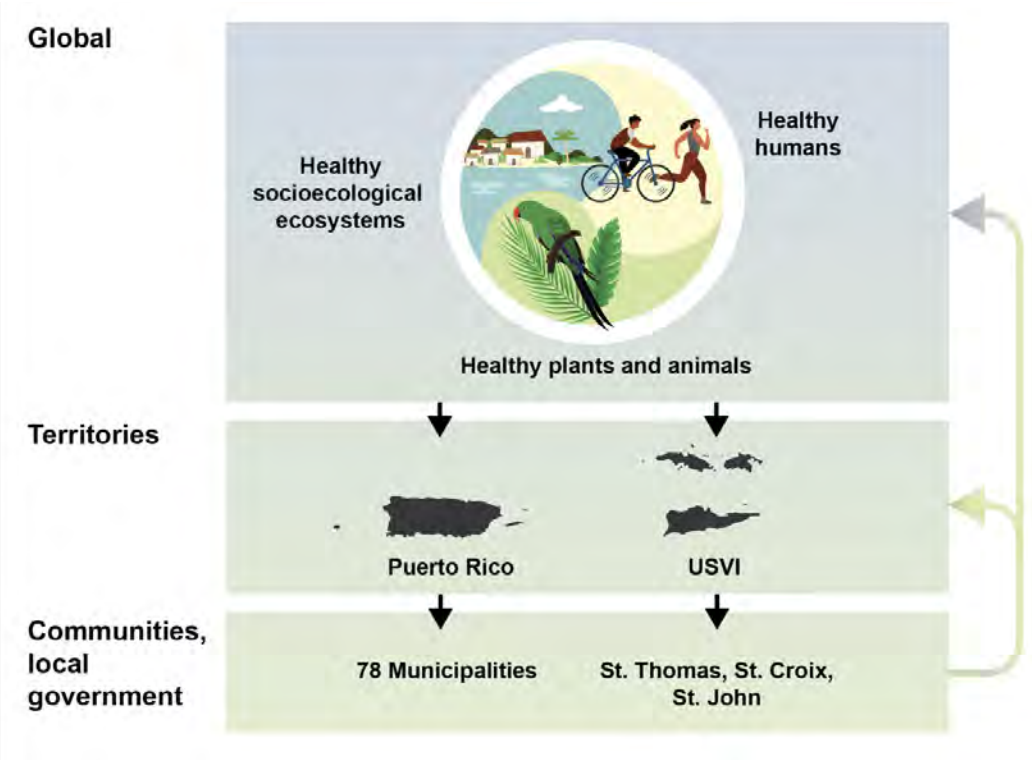
Climate-Driven Extreme Events Exacerbate Inequities and Impact Human Health and Well-Being

Traditionally underserved and disadvantaged communities suffer disproportionate impacts from climate change because they have been systematically excluded from social services, secure livelihoods, quality education, and other social benefits that help sustain health and well-being (*high confidence*). Hurricanes and other climate-related extreme events have been associated with higher rates of disease, mental illness, and overall mortality, as well as loss of cultural heritage that is central to community identity (*high confidence*). As extreme weather events become more intense and more frequent, residents will continue experiencing increasing levels of noncommunicable diseases, excess mortality, behavioral health challenges, and loss of quality of life (*high confidence*). The frequency of heat episodes and the severity of hurricanes are both expected to increase in the region due to human-induced climate change, which will affect public health unless adaptation measures are taken (*high confidence*).

Long histories of colonization and systemic inequality shape the ability of the US Caribbean peoples to maintain health, quality of life, and overall individual and social well-being. Evidence from both PR and the USVI suggests risks from climate impacts to multiple elements of human health, including vector-borne and noncommunicable diseases, mental health, and overall quality of life (Ch. 15).[41] US Caribbean societies, with their multiethnic and multiracial makeup of high proportions of people of African and Indigenous descent, are more vulnerable to climate-related risks due to economic policies and social systems, varying levels of educational attainment, unemployment, poverty, out-migration, older-age demographics, food insecurity, colonialism, and unjust historical treatment.[42] As an effort to address these circumstances and the threat of more frequent extreme events, the One Health approach, similar to the community health concept

described in Chapter 15, mobilizes collaborative work among communities, stakeholders, practitioners, sectors, and disciplines to tackle climate change while improving well-being and quality of life for all living organisms (Figure 23.3).

The One Health Approach



In the face of climate change, the health of Caribbean people, plants, animals, and ecosystems depends on coordination across multiple scales and boundaries.

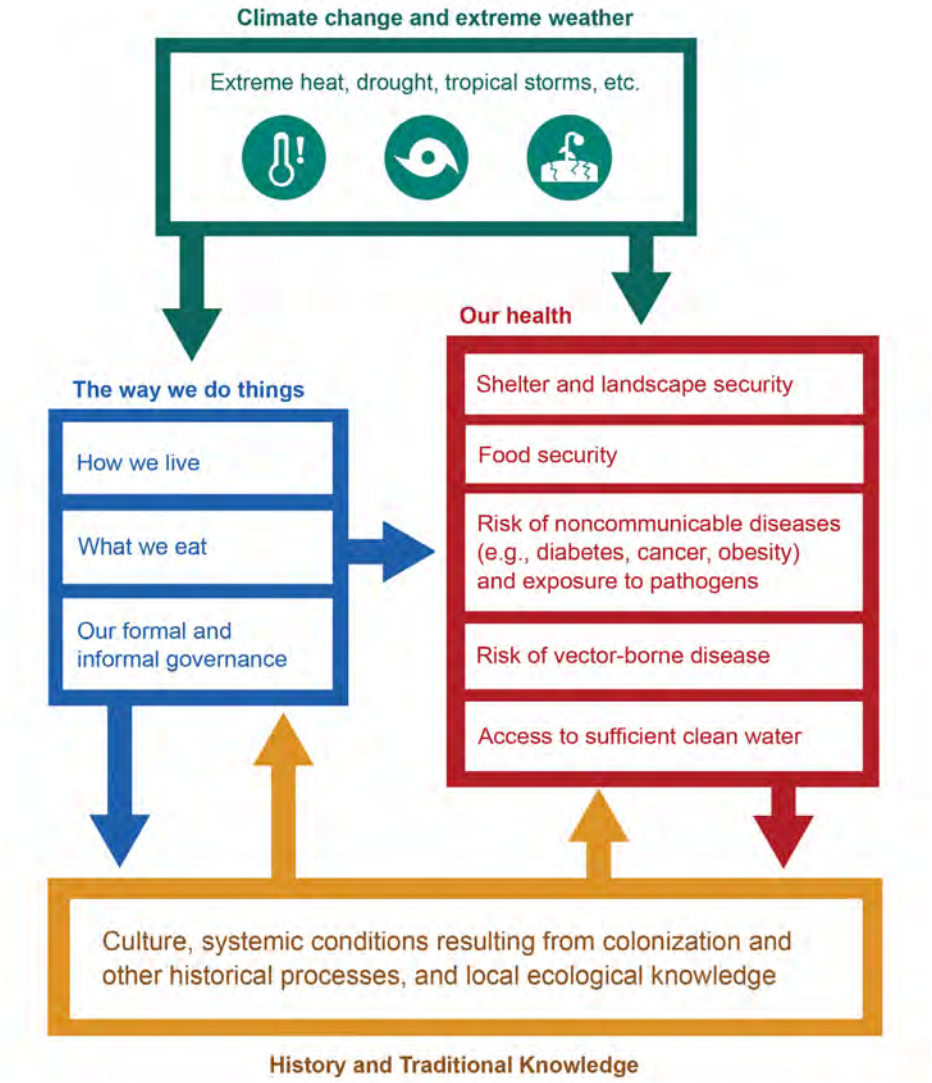
Figure 23.3. In the US Caribbean, climate change is interacting with the institutional and environmental context of the islands and the social determinants of health. Extreme weather events (e.g., powerful hurricanes, extreme heat, and droughts) are threatening access to clean air, safe drinking water, nutritious food, and safe settlements, as well as damaging infrastructure, reducing tourism, displacing vulnerable communities, promoting migration among islanders, disrupting ecosystem services, and endangering animals. The One Health approach illustrated here promotes collaborative work at local, regional, and global levels to achieve health for humans, ecosystems, and animals alike. Adapted from World Health Organization 2021[43] [CC BY-NC-SA 3.0 IGO].

Community Identity and Heritage Are Necessary for Resilience and Post-disaster Recovery

US Caribbean cultural heritage is under threat due to changing climate conditions (Figure 23.4). Cultural heritage includes tangible elements (such as buildings, artifacts, monuments, and archaeological sites on land and underwater) and intangible elements (such as practices, ideas, representations, knowledge, music, songs, and ceremonies) that are recognizable components of community identity.[15,44] Research from recent hurricane events suggests that the magnitude of loss of heritage is severely underestimated[45,46] and that measures to mitigate climate impacts greatly threaten the preservation of cultural heritage and identity. For example, the traditional ways of life in the US Caribbean placed communities next to riverbanks for thousands of years. Archaeological sites associated with such communities, however, are under threat

from flood-control projects,[15] which entail channelizing, dredging, or covering rivers (e.g., USACE 2022[47]). These flood-control projects not only impact archaeological sites but also transform landscapes that are integral to the identity, recreation, and overall well-being of local residents.[15,48] Climate impacts also increase out-migration, which can lead to disintegration of traditional communities and loss of Indigenous and Traditional Knowledge (KM 30.2).[49]

Climate Change and Public Health



Public health is shaped by sociocultural factors and further affected by climate change.

Figure 23.4. The impacts of climate change on human health in the US Caribbean must be considered in the context of the social, cultural, and historical realities of the islands. Shelter and food security, access to clean water, and communicable and noncommunicable diseases are certainly affected by climate, but they are also conditioned by culture, tradition, and historical and colonization processes. Figure credit: University of California, San Diego; University of the Virgin Islands; NOAA NCEI; and CISESS NC.

Impacts of Extreme Events on Health and Essential Services

Extreme events, combined with deteriorating infrastructure and unequal distribution of social determinants of health, are expected to continue to cause interruptions in and insufficient access to healthcare services, as documented after Hurricanes Irma and Maria (KM. 15.2).[14,50,51,52] PR and the USVI have contaminated sites where hazardous waste has been discarded and, in some cases, improperly managed. Some of these sites—26 in PR and 2 in the USVI—are designated as EPA Superfund sites.[53] Extreme flooding has the potential to impact Superfund sites, spreading large amounts of contaminants and carcinogens into the surrounding environment.[54]

In the aftermath of Hurricane Maria, many older adults in PR experienced unmet needs that contributed to declining physical and emotional health, inadequate management of noncommunicable disease (NCD), social isolation, financial strain, environmental health issues, and excess mortality.[14,55,56] High levels of post-traumatic stress disorder (PTSD), depressive symptoms, and disaster-related stressors were also evident (KM 30.2).[42,57] Many hospitals suffered significant damages in both territories.[58] Various healthcare services were greatly affected, including vaccinations, cervical cancer screenings, surgeries, oncologic treatments, and dialysis.[59,60,61,62,63,64] Experts recommend that further disease-specific planning be delineated within the emergency response of each jurisdiction and in collaboration with disease-specific plans for relevant organizations.[65] For instance, region-specific and federal health plans, such as the CDC's comprehensive cancer control plans, would mitigate the impact of extreme weather on specific populations and maintain adequate cancer prevention and treatment care during and after disasters.

Noncommunicable Diseases

The US Caribbean territories have high rates of NCDs, as well as increasing rates of impaired mental health.[42,66] After Hurricane Maria, there were obstacles to providing nutritious, affordable, and culturally acceptable food appropriate for people with NCDs.[42] In PR and the USVI, 67.5% and 65.2% of the population, respectively, are overweight, and 31.4% and 32.5% live with obesity;[67] these conditions are considered predictors of early mortality.[68] Surveys in PR in 2017 and 2019, pre- and post-Hurricane Maria, show an increase over that time span in the prevalence of NCDs and depression in adults.[69] In March 2018, an online survey identified PTSD in 44% of respondents in PR and 66% of those displaced from PR to Florida.[70,71]

Climate-Driven Vector-Borne Diseases

Vector-borne diseases (VBD) in the Caribbean, such as dengue, Zika, and chikungunya, are mostly transmitted by the *Aedes aegypti*, *Aedes albopictus*, and *Culex* mosquitoes (KM 15.1). The abundance of *Ae. aegypti* and *Ae. albopictus* are influenced by temperature and precipitation, and both species have excellent adaptation skills under extreme temperature and precipitation conditions.[72,73,74,75,76] Factors in the US Caribbean that favor VBD outbreaks include climate change, inequality, poverty, serotype profile (virus variation), immunity, deficient water and waste management, and lack of community awareness.[75]

Climate Impacts on Human Zoonotic Diseases

Human leptospirosis is an important zoonotic disease—that is, a disease that transmits from animals to humans—with worldwide distribution. It was first reported in PR in 1942, while the first cases of leptospirosis in the USVI were reported in the aftermaths of Hurricanes Irma and Maria. Recent evidence suggests an excess risk in PR of leptospirosis associated with flood-prone areas, heavy rainfall, and higher temperatures.[77] Extreme weather events such as tropical storms, heavy rainfall, and floods are expected to result in an upsurge in the number and magnitude of leptospirosis outbreaks.[78] Under the above-mentioned climate scenarios, outbreaks in both US territories are *very likely* to occur following extreme weather events.

Excessive Heat and Differential Social Burden of Climate Impacts

Heatwaves are increasing the risk for heat-related illness and death (KMs 6.2, 15.1; Figure 15.1). Conditions of extreme heat in the Caribbean have intensified since 1980. Recent research suggests an increasing trend in the number of days with heat stress (days above 39.9°C [103.8°F]) for the Caribbean region since 1980.[79] Several factors contribute to heat vulnerability and sensitivity, including:

- Populations at the extremities of age (e.g., newborns, children, elders)
- Pregnant women/people
- Individuals who are
  - living in single-person households
  - living below the poverty line
  - working in confined spaces with poor ventilation
  - working outdoors and exposed to risk factors such as direct sunlight or high humidity combined with extremely high air temperature
  - living with disabilities
  - living with chronic health conditions (e.g., obesity, hypertension, diabetes, cardiovascular disease, respiratory illness)
  - without health insurance coverage

With rapid urbanization in the USVI and PR and past population growth, urban heat island effects have become stronger (KM 12.2). San Juan, PR, is already showing evidence of these effects;[80] extreme heat episodes there have been associated with a significant increase in mortality and an increased relative risk for stroke and cardiovascular diseases.[81] Cooling indoor environments help lessen the impact of heatwaves, but energy demands on a crumbling power infrastructure, as well as rising costs of living, create climate risks associated with inequality, as only a section of the society will be able to afford cooling equipment.[82]

Human Health and Natural Sources of Air Pollution

Recent studies suggest that global warming will make dust storms more severe in the Mediterranean and the Atlantic (KM 14.1).[83] In the US Caribbean, dust particles carried across the Atlantic from the Sahara, mostly during summer, affect climate, weather, and ecosystems, including coral reefs, forests, and human populations.[84,85,86,87,88,89,90,91,92] Saharan dust provides nutrients to terrestrial and marine ecosystems. However, in PR, Saharan dust has been associated with increased cardiovascular and respiratory risks;[93] it has also been linked to increased risk of emergency room visits and hospitalizations related to asthma in children in Trinidad and Tobago,[94] Guadeloupe,[95] and Grenada.[96] As humidity and temperatures rise, the abundance of mold and spores in the air also impacts air quality and thus respiratory NCDs.

Sargassum and Health Intersections

Sargassum is a brown seaweed that floats in the Atlantic Ocean and provides an important habitat for migratory organisms that have adapted specifically to it. These algal mats are sometimes pushed by wind and currents into the Caribbean Sea and are frequently reaching the coasts of the region's islands. Evidence suggests that these events threaten coastal ecosystems and social and cultural activities (e.g., fisheries), with negative economic impacts (e.g., reduced tourism and degraded infrastructure; Ch.10; KM 1.2) and adverse human health effects (e.g., heart palpitations, shortness of breath, and skin rashes) due to hydrogen sulfide from decomposing sargassum in the air and direct exposure to algae.[97,98,99,100,101,102,103] While sargassum mats can be harvested for beneficial uses such as fertilizer and animal feed and as an energy source, its use as a fertilizer could transfer heavy metals to crops.[104,105,106] While the impact of this phenomenon has not yet been assessed for the US Caribbean, these conditions are expected to worsen as climate change intensifies.

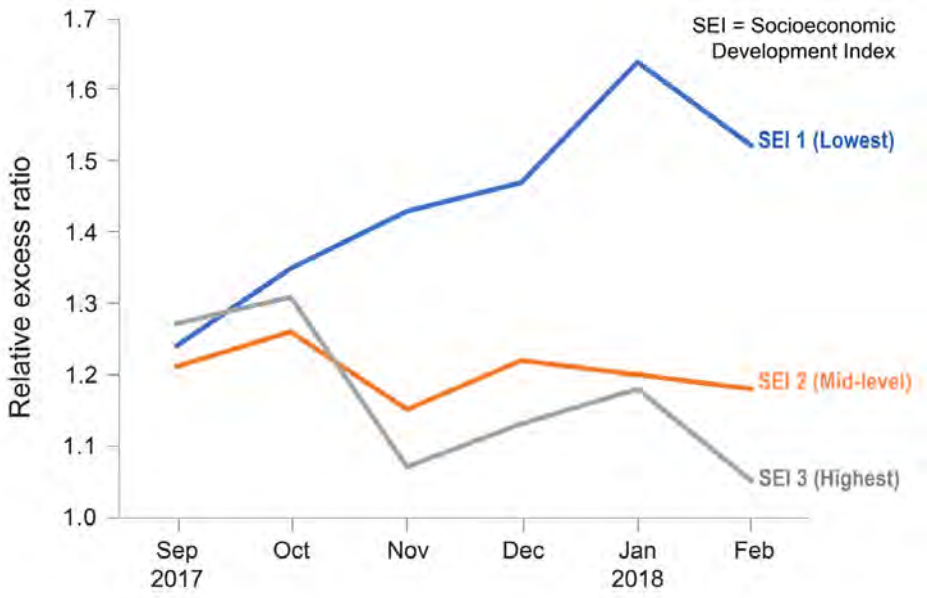
Water Resources and Human Health Interactions

Factors related to environmental health and changing climate (e.g., sea level rise, saltwater intrusion, and pollution) impact water security. Inefficient water management and climate change, including the increasing intensity of storms, have led to growing concerns about water scarcity and water insecurity for both territories.[107] While Traditional Knowledge has been shown to mitigate water scarcity during emergencies—such as individuals and communities activating historic or abandoned water sources during recent disasters[44,108]—these responses might not be enough, as Traditional Knowledge is also threatened, cultural heritage is being lost, and the magnitude of impacts exceeds previous experience (KM 30.1). Older traditional farmers in Puerto Rico have recorded a reduction in freshwater availability in streams and springs that impacts their traditional access to fresh water and their food production, which they consider a heightened risk for their health.[15] Reports on communities in both PR and the USVI that are systematically excluded from welfare, education, and other social services and benefits link inequity to poverty levels and the impact of status on the development and interpretation of laws and programs that address these issues (KM 15.2). Studies after hurricanes in PR and the USVI have shown water pollution, disease vectors, and bacteria in the drinking water supply, all of which are expected to worsen with expected impacts of climate change, thus affecting livelihood security.[109,110,111]

Underestimation of Mortality

Total excess mortality identifies how many more observed deaths happen after a specific event in comparison to the baseline historical trend of expected deaths had the natural event not occurred. After Hurricane Maria in PR, a large excess mortality was noticed by many people but not identified by the official certification of 64 deaths. Six months after Maria, a commissioned independent study identified 21% more deaths in males than expected and a total excess mortality estimate of 2,975 (Figure 23.5),[56] including both direct (related to hurricane injuries) and indirect (related to lack of access to effective care after the storm) deaths. These deaths mostly affected the most vulnerable populations, including those at lower socioeconomic levels.[56] The distribution of causes of excess mortality is predominantly driven by chronic noncommunicable diseases.[112] Further analysis estimated 514 excess deaths in the Puerto Rican population displaced to the US mainland.[113] Evidence shows that considering only direct hurricane injuries greatly underestimates the overall impact on excess mortality. After Hurricane Fiona in 2022, the mortality in Puerto Rico was 1.15 times higher in adults older than 75 years of age, who experienced 226 excess deaths.[114]

Excess Mortality from Hurricane Maria in Puerto Rico



Excess mortality from Hurricane Maria was most common among Puerto Rico's most impoverished residents.

Figure 23.5. Between September 2017 and February 2018, 2,975 excess deaths—that is, above what the mortality rate would have been if the storm had not occurred—were estimated in Puerto Rico due to Hurricane Maria. Mortality was higher for individuals living in low-income municipalities, for those with the lowest scores on the Municipal Socioeconomic Development Index (SEI)—a multidimensional index of poverty developed by the Government of Puerto Rico—and for men aged 65 years or older. These results are useful to health officers, emergency preparedness personnel, and residents, as they help to prepare for and to mitigate the potential effects of hurricanes. Adapted from Santos-Burgoa et al. 2018.[115]

Key Message 23.2

Ecology and Biodiversity Are Unique and Vulnerable

Coastal and terrestrial ecosystems provide a large number of goods and services that are vital to the islands' economies and to the health and well-being of their residents (*high confidence*). These essential systems are degraded by human actions and climate change, thereby reducing the benefits they provide to people, as well as their functionality as habitats for protecting biological diversity (*high confidence*). Climate change is expected to exacerbate the degradation of ecosystems (*very likely, high confidence*). The success of climate adaptation strategies will depend on reducing all sources of stress on ecological systems (*medium confidence*).

PR and the USVI are home to diverse aquatic and terrestrial ecosystems and are rich in natural resources and cultural heritage. Residents depend on the region's natural resources and ecosystem services for their well-being and livelihoods. These important ecosystems are being degraded by economic activity, habitat destruction, land conversion, pollution impacts, and overfishing.[116] Climate change impacts on land will have environmental consequences along the coast and beyond. Impacts and consequences will vary by territory, species, and ecosystem type.

Impacts of a Changing Climate on Ecosystem and Biodiversity Goods and Services

Climate stressors (e.g., extreme precipitation, droughts, frequent and intense tropical cyclones, and steady increases in surface temperatures) and non-climate stressors (e.g., pollution and deforestation) interact to impact ecosystems and the services they provide to people (Ch. 9). Ecosystem services include provisioning services such as food, feed, and fiber; regulating services such as climate regulation, flood control, and air and water purification; cultural services such as recreation and spiritual and aesthetic benefits; and supporting services such as nutrient cycling, primary production, and soil formation.[117] Climate change is increasingly compromising ecosystem goods and services (Ch. 8).

Coastal zones—often highly valued and the focal point for cultural activities, Traditional Knowledge, tourism, and industries essential for economic and social vitality—are at risk from climate change (KM 9.2).[118,119,120] The US Caribbean coastline is roughly 876 miles (1,410 km) in length (PR, 700 miles [1,127 km]; USVI, 175 miles [282 km])[121] and is composed of nested coastal ecosystems such as sandy dunes, beaches, mangroves, salt flats, coral reefs, and seagrass beds. The high population density, concentrated development, and critical infrastructure located within 0.6 miles (1 km) of the coastline are highly vulnerable to coastal hazards and climate stressors.[20] The combined destructive power of wave action and intense rainfall from Hurricanes Irma and Maria alone damaged over 12% of coral reefs,[122,123,124] caused beach loss of 1.2–3.1 miles (2–5 km),[119,125,126] eroded dunes,[118,127] and devastated almost 33% of mangroves.[128] These impacts added to the degradation of ecosystems caused by other climate stressors (KM 8.2).

The loss of recreational benefits from the degradation of coastal reefs is expected to reach $172 billion (in 2022 dollars) by 2100 under a very high scenario (RCP8.5).[129,130,131] In 2019, an assessment quantified the annual coastal flood risk-reduction benefits provided by all US coral reefs, including those in PR and the USVI, as illustrated in Figure 23.6.

Annual Expected Benefits from Coral Reefs in the US Caribbean

Coral reefs provide substantial coastal protection benefits to the US Caribbean each year.

Figure 23.6. Coral reefs are a major component for recreational and commercial fisheries, coastal protection, and the tourism economy. Acting as a natural defense, coral reefs dissipate incident wave energy and protect coasts from erosion and flooding. Arguably, they are one of the most economically valuable ecosystems.[130] Economic estimates are in 2010 dollars. Figure credit: Caribbean Coastal Ocean Observing System.

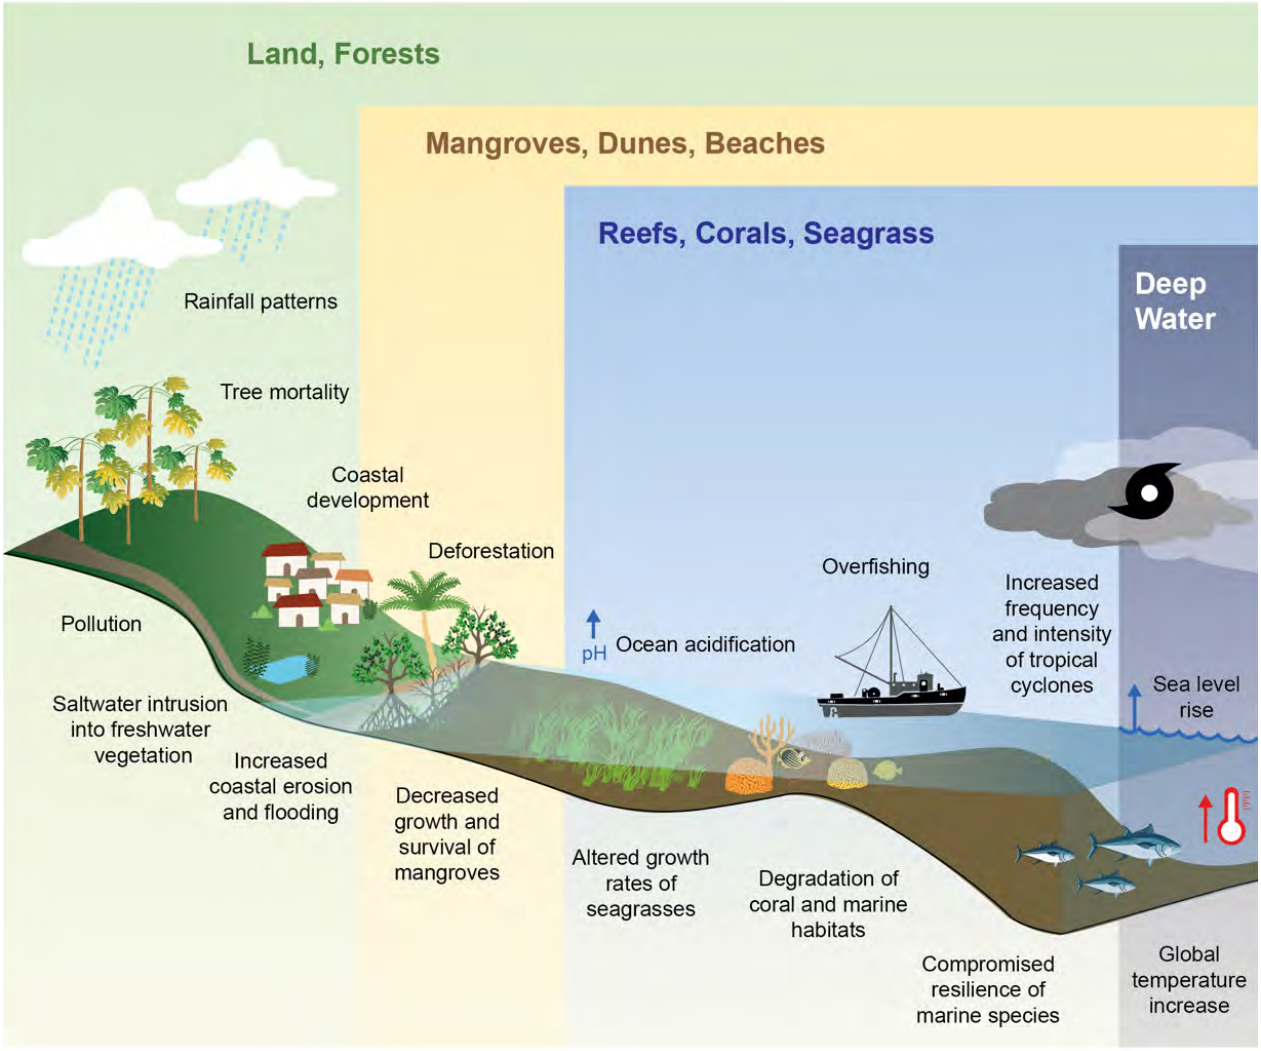
Sediment and contaminant runoff derived from various land-based activities also threaten coastal ecosystems.[125,132] Runoff of land-derived sediment could directly impact coral regeneration capacity, growth, and mortality, as well as the ecosystem services they provide.[93] Cross-jurisdictional strategies and ecosystem-based management principles must be adopted to significantly reduce the adverse impacts of anthropogenic/land-derived pressures on coastal ecosystems.[133] In PR's Guánica Bay watershed, for example, a watershed management plan is being implemented to restore the health of coral reefs damaged by sediment and nutrient runoff.[134]

Caribbean forests are highly diverse, ranging from coastal mangroves to dry forests. These ecosystems provide many services, including habitat, recreation, coastal protection, and improved air and water quality.[135] Although forests are adapted to withstand frequent natural disturbances, projected changes in temperature and rainfall are expected to impact the amount of fruiting and flowering, tree productivity, and nutrient cycling, as well as increase the likelihood of tree mortality, among other impacts (KM 7.2). Furthermore, they can alter the forest ecosystem's biogeochemical processes and affect their composition, structure, and functioning.[136] For example, trees within northeastern PR are already operating above their optimum temperature for photosynthesis; thus, increasing temperatures (which are projected) will lead to the release of more carbon dioxide (a major driver of climate change) into the atmosphere.[137,138,139] Meanwhile, research on tropical forestry, ecology, and conservation in the Luquillo Mountains in PR has reversed the paradigm that tropical ecosystems are fragile, demonstrating instead that they exhibit remarkable resilience to many forms of disturbance.[140]

Emerging Issues and Future Directions

Ecosystems that are already degraded or stressed may have lower adaptive capacity and resilience. Increased stress from climate change may drive ecosystems to tipping points,[141] with potentially irreversible socioeconomic consequences for coastal socioecological systems and community livelihoods.[141] Maintaining, enhancing, and/or restoring ecological connectivity and corridors as conservation strategies are key to helping ecosystems adapt to climate change (Figure 23.7; Ch.1; KM 3.6).

Ecosystem Stressors



Both climate and non-climate stressors affect aquatic and terrestrial ecosystems and biodiversity in the US Caribbean.

Figure 23.7. The cumulative effects of these stressors could result in the degradation of aquatic habitats, increases in coastal erosion and flooding, tree mortality, alterations in the growth of mangroves and seagrasses, and diminishment of resilience and adaptive capacity. Adapted with permission from Fitzpatrick and Giovas 2021.[142]

Key Message 23.3

Climate Change Threatens Water and Food Security

US Caribbean food and water systems are becoming increasingly vulnerable to the escalation of climate change, including stronger hurricanes, more severe drought, warmer air temperatures, and other extreme weather (*likely*, *high confidence*). Because the territories are heavily reliant on imported foods, they are affected by climate changes occurring both within and outside of the region (*high confidence*). Reductions in average annual rainfall, increasing air temperatures, and rising sea levels will adversely affect freshwater availability in the future (*medium confidence*). Improved adaptation efforts would benefit from a better understanding of the ways food and water systems interrelate and of the cascading impacts generated by climate change (*medium confidence*).

Food and water security are important for well-being and emerge from complex social and environmental interactions across groups and regions in the Caribbean. About one-third of Puerto Rican adult residents in 2015 lacked consistent access to adequate food, higher than the rate on the US mainland (12%).[143,144,145] Low-income households were more than three times as likely to experience food insecurity as households with higher income.[145] These numbers are influenced by lower governmental expenditures for key economic security programs relative to other US states or territories.[146]

Within this context, climate change can deepen food and water insecurity in the region.

Characteristics of the Island Food Systems

More than 80% of the food consumed in PR comes from the US mainland[147,148,149] on US-flagged ships, as required by law.[150] Most of the food imported by PR arrives at a single port of entry and is transported by only a few maritime companies.[151] In PR, food imports have been increasing since the 1950s.[151,152]

The agricultural sector represents an important source of employment and food security, although production accounts for less than 1% of the GDP in Puerto Rico.[153] Between 2012 and 2018, the total number of Puerto Rican farms declined by 37%, with farms less than 10 acres in size declining by about 57%.[154] The main classes of production are plantains and bananas, coffee, root crops and tubers, fruits and vegetables, nursery crops, and grasses.[154] Cattle and dairy production generate more than 25,000 jobs on the island and occupy more than 50,000 acres.[155,156]

The USVI imports more than 90% of its food, with importation of most food categories increasing over time.[157,158] The main crops grown and sold on the islands are vegetables, nursery crops, and tree crops. Between 2007 and 2018, the sale of these main crops increased by 1.1%, but they still represent less than 1% of GDP.[159,160]

Characteristics of the Island Water Systems

In PR, approximately 82% of water used is derived from surface water sources (reservoirs and streams), with the remaining 18% extracted from groundwater sources.[161] The total storage capacity in reservoirs is decreasing due to sedimentation.[162] Rain harvesting and desalination plants are also sources of potable water, primarily in the USVI. There is a tension between water for consumption and agricultural uses. PR has four irrigation districts around the main island that draw on a network of reservoirs to provide water to farmers for crops via irrigation canals. The Puerto Rico Aqueduct and Sewer Authority (PRASA) also purchases rights to the water in the districts. Water from PRASA is expensive and cannot be used for

agriculture.[149] Due to faulty infrastructure, mismanagement, evaporation, and theft, approximately 50% of water purchased by PRASA from the irrigation districts is lost before reaching the public.

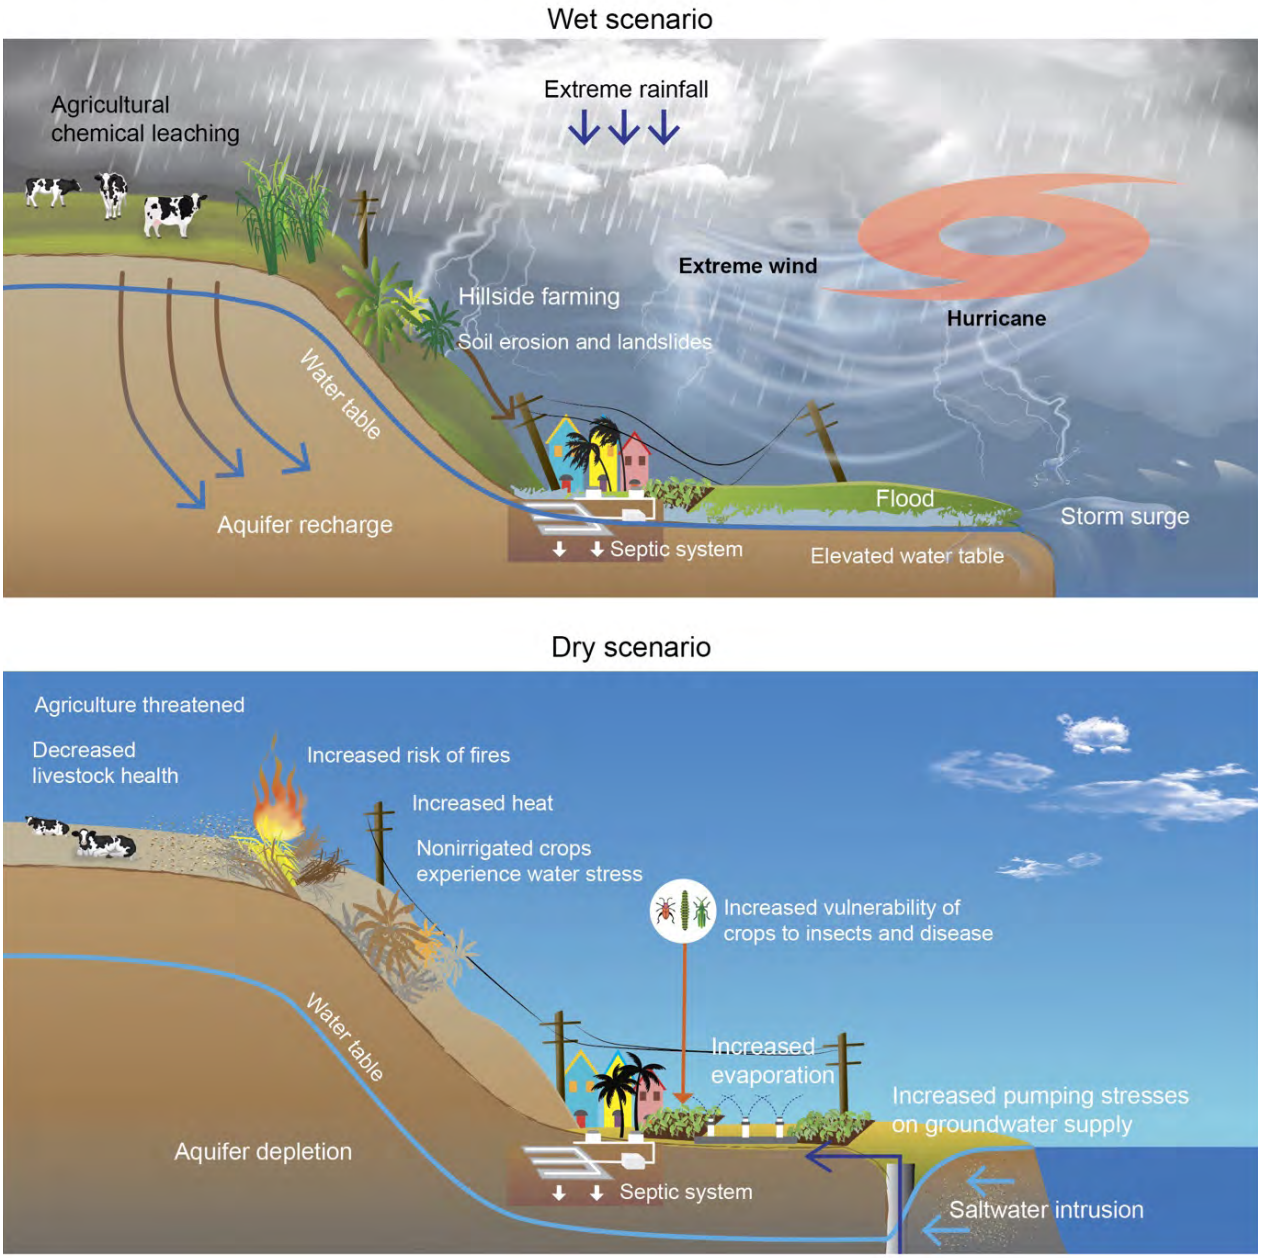
Outside of these four irrigation districts, surface runoff is stored in ponds or pumped from aquifers. The South Coast aquifer (SCA) has declining water levels due to over-pumping, which in some cases has lowered the water levels below sea level, leading to salinification.[163,164,165] The cost of water to farmers is low,[149] which may discourage them from using water efficiently. Irrigation scheduling can be used to optimize irrigation water use;[166] however, limited data exist on the irrigation scheduling methods used by farmers in PR and the USVI. About 10%–20% of the water introduced into the irrigation canals is lost by leakage.[161]

In the USVI, farmers access water from surface ponds and aquifers and from stored rainwater in cisterns. On St. Thomas, the majority of the farming occurs in the drier Estate Bordeaux.[167] Farmers there depend mostly on private and public cisterns and ponds or on wells that are privately managed. On St. Croix, most farmers depend on groundwater from deep wells or water from private cisterns or ponds they own or that are managed by the USVI Department of Agriculture. On St. John, farmers capture water in privately owned ponds. Few farmers depend on the public water system.

Climate Stressors on Food and Water System Components

Climate change is affecting and will continue to affect the region's food and water systems (Figures 23.8, 23.9).[147] In the past, strong winds and heavy rain have destroyed crops and caused livestock mortality. They have also led to landslides, soil erosion and degradation, flooding, and sediment contamination of water.[168] Between 1995 and 2017, agricultural losses attributed to hurricanes in PR accounted for 3%–26% of the total estimated economic damages. Hurricane Maria in 2017 alone caused more than $2.3 billion (in 2022 dollars) in losses and damages to crops and infrastructure,[169] which represented a reduction of about 80% of the main island's total agricultural value.[170] Beyond these direct impacts, a substantial portion of agricultural losses were caused by indirect effects of tropical cyclones, including energy outages, disrupted telecommunication and water supplies, and damaged roads and irrigation systems.[152,168,171] With a projected increase in the intensity of major tropical cyclones, these impacts are expected to worsen without investments to make food and water systems more resilient (KMs 8.3, 11.3, 30.1).

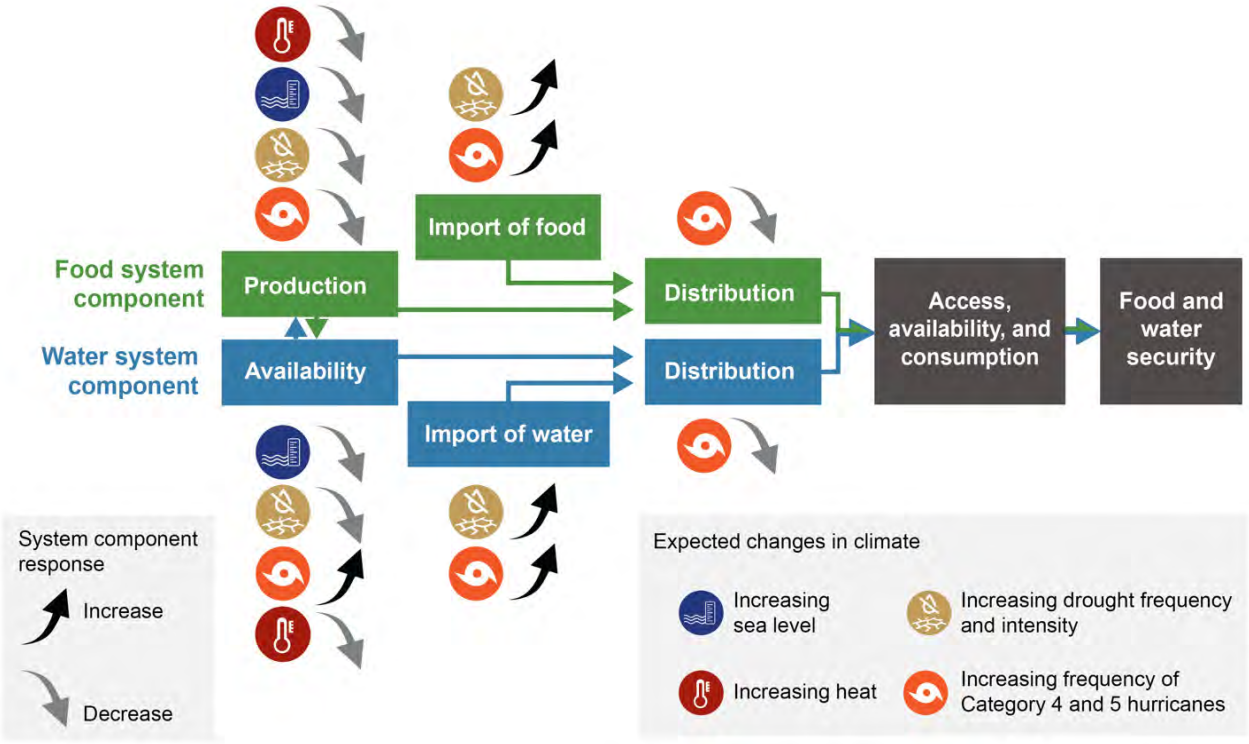
Climate Impacts on Food and Water Systems from Ridge to Reef



Risks to food and water systems differ under wet and dry scenarios.

Figure 23.8. (**top**) In periods of wet conditions, saturated soils coupled with heavy rainfall from hurricanes and storms can lead to flooding and, in turn, soil erosion and vegetation and crop destruction. Strong winds and floods can also damage infrastructure needed for food and water distribution. Excessive rain combined with higher sea levels affects water quality through the leaching of agricultural chemicals and wastewater from septic systems. (**bottom**) Dry conditions, on the other hand, increase groundwater pumping for irrigation. When combined with sea level rise, these conditions can also lead to saltwater intrusion into coastal aquifers. Figure credit: University of Puerto Rico, North Carolina State University, USDA Forest Service, University of Arizona, and University of the Virgin Islands.

Food and Water Systems



Cascading impacts of climate change affect food and water systems and security.

Figure 23.9. The figure displays the effects of the main climate changes that directly affect the islands on each of the system's components. The up and down arrows show the increasing or decreasing effect of a given climate change stressor on the food or water system components. For example, the increasing frequency of Category 4 and 5 hurricanes will cause a decrease in the distribution of food and water. The effects of climate changes are moderated by external influences such as socioeconomic changes that precondition the islands to be more or less susceptible to climate changes. Figure credit: University of Puerto Rico, USDA Forest Service, University of Arizona, North Carolina State University, and University of the Virgin Islands.

Drought has been common to PR and the USVI. Between 1950 and 2016, periods of severe drought occurred across the Caribbean (1974–77, 1997–98, 2009–10, and 2013–16). Regions of PR in 2020 and the USVI in 2021–2022 were declared by the USDA to be natural disaster areas because of drought conditions. The 2014–2016 drought was characterized as the most severe on record.[172] Livestock losses in 2015 accounted for about 62% of all reported economic losses, and plantain losses accounted for 22%. The combination of periodically dry conditions with a warming trend leads to aridification and compounding impacts (KM 4.1).[173] Aridification leads to increased demand for irrigation. Higher demand for irrigation, coupled with salinification of aquifers from sea level rise, suggests that groundwater aquifers like the SCA will be under increasing pressure in the future. Following 2015, the government of Puerto Rico created the Scientific Drought Committee. The USDA Caribbean Climate Hub created the Caribbean Drought Learning Network in 2021 to integrate drought-related information, initiatives, and programs in PR and the USVI.[174] These initiatives can help preparation and response to future droughts.

Increasing average and intermittent extreme temperatures are expected to reduce crop yields,[175] especially in tropical regions.[176] Expected impacts on crops include reduced seed yield,[177] reduced pollen production, and increased rate of senescence (i.e., shortening of a crop's life cycle).[178] The negative effects of increasing

temperature worsen under water deficit conditions.[178] Higher temperatures also increase the potential for wildfires;[179] can affect the range of weeds, diseases, and insects;[180] and can cause heat stress in farmworkers (KM 4.2).[181] Increased atmospheric CO_2 levels may counteract the negative impacts of higher temperatures; however, adequate water is required to take advantage of CO_2 fertilization.[182] Crop water use may increase[183,184,185] or decrease[186] under climate change conditions, depending on site-specific changes in the meteorological parameters.

Both drought and elevated temperature have negatively impacted livestock producers in PR and the USVI.[152,156] High temperatures lead to heat stress, which reduces animal productivity, increases the proliferation and survival of parasites and disease pathogens, reduces the ability of dairy cattle to produce milk and gain weight, and lowers conception rates. Furthermore, bovine breeds in PR and the USVI are more susceptible to heat because they were largely introduced from temperate regions, such as from within the US mainland.[155,156]

Soil health has direct effects on the ability to maintain agricultural production in the future and to adapt to climate change. Soil organic carbon is affected by increasing temperatures. Both mineralization and the loss of organic carbon and nitrogen increase under elevated temperatures.[187] Extreme variation in rainfall can promote carbon loss via soil drying and soil erosion. Certain conservation practices—such as no-till farming and the use of cover crops—can promote soil health and enable the sequestration of larger amounts of carbon in the soil.[187,188,189] The USDA Natural Resources Conservation Service is promoting methods to increase soil health in PR and the USVI.[190]

Social Protection

Crop insurance plays an important role in reducing climate impacts. In PR, about 50% of farmers participate in the Puerto Rico Crop Insurance Corporation (PRCIC; a similar program is currently unavailable in the USVI). Between 2010 and 2019, the PRCIC paid compensation for agricultural losses for 25 events, all but one—a wildfire—related to rainfall (hurricanes, tropical storms, tropical depression floods, and extreme rains). Ninety-eight percent of the total insurance payouts for the 2010–2019 period was for losses caused by hurricanes. The insurance program, however, does not cover drought.[152]

Emerging Issues

Areas receiving increased attention essential to managing extreme weather include plant and animal breeding,[156,191] crop production within controlled environments,[192] precision agriculture,[193] irrigation scheduling,[194,195] and flood and drought early warning systems.[196,197] Increased local food production and the need to balance water use among sectors will become increasingly important issues.[149] In the USVI, the lack of information to quantify economic losses associated with climate impacts, such as the effects of drought on food and agriculture, is also an issue. Superimposing climate change on top of other compounding issues (internal and external) will create additional stressors and have cascading impacts on food and water systems within the region. Understanding the complexity of the islands and their food and water systems will aid in the creation of contingency planning for problems that may arise.

Key Message 23.4

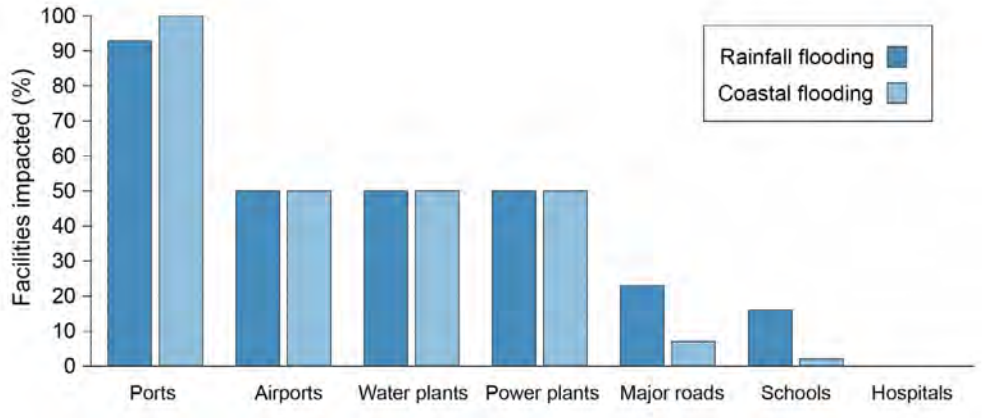
Infrastructure and Energy Are Vulnerable, but Decentralization Could Improve Resilience

Climate change has created profound risks for the US Caribbean's critical infrastructure, already weakened from years of disinvestment and deferred maintenance (*high confidence*). Increasingly powerful storms, along with rising sea levels, are severely impairing infrastructure systems, with increasing damage projected in future years (*likely*, *high confidence*). Dependence on fossil fuel imports increases energy insecurity (*high confidence*). Infrastructure improvements, coupled with a new paradigm focused on decentralization, adoption of distributed solar, and shared governance, could help limit residents' vulnerability to health and other risks associated with loss of essential services (*likely*, *medium confidence*).

The 2017 and 2022 hurricane seasons in the Caribbean demonstrated the vulnerability of critical infrastructure (e.g., energy, water, healthcare, transportation, telecommunications, wastewater, stormwater, and solid waste) in Puerto Rico and the USVI to natural hazards.[23,24,198] This vulnerability is mainly caused by years of deferred maintenance, the recurrence of powerful tropical storms,[199,200] and a centralized mode of production and governance that limits redundancy, flexibility, and, therefore, the ability to anticipate and adapt to future scenarios that climate change will create.[201,202,203,204,205]

Powerful tropical storm impacts are exacerbated by higher sea levels, which increase storm surge and prevent proper drainage of higher stormwater volumes.[12,21,25,206,207,208,209] As a consequence, critical infrastructure systems, which tend to be concentrated near the coasts and floodplains, will experience compounded effects of different hazards and disrupt the movement of people, goods, and services (Figure 23.10; KM 9.2).[204,210] Climate change is also causing higher temperatures and drier conditions,[12,21,211] thereby reducing water availability, increasing water demand, and intensifying saltwater intrusion into aquifers.[212,213] And, because infrastructure systems are interconnected and interdependent, the disruption of any single system will affect the operation of other systems. Currently, even outside of droughts, water for human needs competes against demand for power production (KMs 4.2, 5.1).[214] Similarly, even without hurricanes, sea level rise affects the operation of marine, air, and surface transportation systems,[204] and stormwater flows overwhelm wastewater systems.[200,204]

Infrastructure at Risk of Flooding in the US Virgin Islands



Many types of facilities in the US Virgin Islands and Puerto Rico are threatened by storm-induced flooding.

Figure 23.10. The figure shows the percentage of critical infrastructure currently located in flood zones (rainfall flooding caused by rainstorms and coastal flooding caused by storm surges and waves) in the US Virgin Islands. Many similar facilities are at risk in Puerto Rico,[215,216] but data are missing to represent the information in this report. Facilities at risk of flooding or that are flooded might not be able to provide critical services to communities when flooded, and there might not be another alternative available. The figure shows vulnerabilities under current climate conditions; additional flooding caused by sea level rise or potential future increases in intensity and duration of rainstorms is not included. Figure credit: University of the Virgin Islands, NOAA NCEI, and CISESS NC.

Increasing temperature and heatwaves will drive power and water demand, and wetter storms will increase demand on wastewater and stormwater pumps.[217,218] Damage from increased rainfall rates from hurricanes and increased hurricane intensities are projected to increase solid-waste flows, and response and recovery activities may intensify the use of single-use items such as utensils or water bottles.[24,219,220] Demand for healthcare is also expected to increase as communities experience higher temperatures or greater exposure to stormwater or wastewater and associated waterborne pathogens.[221]

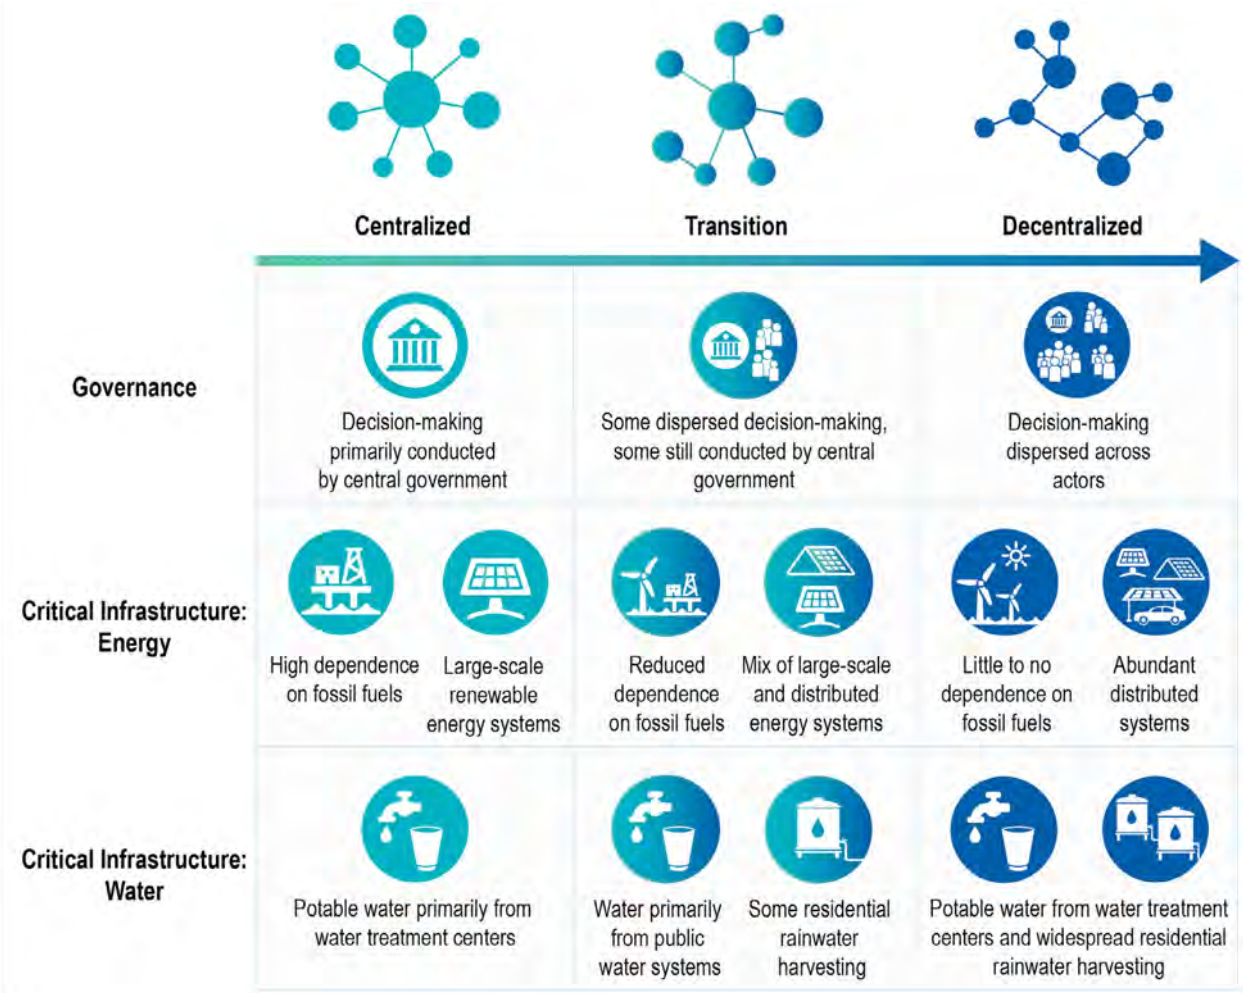
The effects of climate change on infrastructure systems are compounded by human impacts on ecosystems. Ecosystem degradation (e.g., beach erosion, loss of coral reefs or mangroves) is also increasing hazard impacts on infrastructure.[222,223,224,225] Similarly, increased sargassum seaweed[226] can impair infrastructure and render it inoperative, as well as affect the health of the people operating these systems.[227,228,229]

Finally, climate change compounds the stress on already-strained infrastructure systems. Legacy challenges, including systemic lack of investment, mismanagement, and fiscal limitations, undermine the capacity to invest in adaptation activities or to maintain a competitive edge in retaining talent and updating technical capacity.[199,230,231]

Dealing with climate hazards while mitigating other risks will require new thinking about the pitfalls of existing approaches and the potential for a path that allows for better management of resources and service delivery. Highly interdependent infrastructure systems with centralized operation and management structures might be unable to anticipate and adapt to disruptions caused by future climate conditions.[202,232,233] Successful infrastructure adaptation strategies may require restoring natural infrastructure systems (e.g., aquifers, mangrove wetlands, nearshore coral reefs, etc.) for provision of services.[234,235,236] It also may require the adoption of a new paradigm, such as more decentralized infrastructure systems and different models of governance (KM 18.4). For example, household rainwater harvesting protects against prolonged public water system interruptions;[237] sustainable material management reduces pressure on landfills;[238] and microgrids and community solar and household solar systems provide power during inter-

ruptions from the centralized utility (Figure 23.11). These types of decentralized systems can help achieve mitigation targets[239,240,241,242] while also reducing negative health impacts of fossil fuel plants.[243] However, it is important to consider whether or how the adoption of these new systems could exacerbate existing inequities of access to services or to these technologies,[203,244,245] or compete against other land-use opportunities such as farming and housing.[246]

Decentralizing Infrastructure and Governance



Strengthening the resilience of infrastructure will require a transition to decentralized systems as well as decentralized modes of governance.

Figure 23.11. For power systems, decentralization means not only investing in more renewable energy systems managed by utilities but also increasing investments in systems managed by communities and households. For water systems, decentralization means increasing investments in water harvesting infrastructure to serve as an alternative. The improvement of governance models, by decentralizing decision-making and resource allocation, will better address climate change threats and current system frailties and problems. Figure credit: University of the Virgin Islands, NOAA NCEI, and CISESS NC.

Infrastructure systems in the Caribbean are at risk of future climate events, but current operation and management approaches increase their vulnerability.[199,200,230] Further research on infrastructure systems, including community-based solutions to climate challenges, could help identify appropriate paths for adaptation.

Key Message 23.5

Adaptation Effectiveness Increases When Coupled with Strategic Governance and Planning

Climate adaptation in the US Caribbean is challenging because of multiple interacting factors, including high risk exposure, limited or misaligned funding, insufficient institutional and organizational capacity, and siloed approaches to risk reduction and resilience (*high confidence*). Effective adaptation to support resilience in the US Caribbean could be enhanced through co-development and integration of robust global, regional, and local climate science and risk-based knowledge into planning and implementation, as well as improved governance arrangements (*high confidence*). US Caribbean capabilities in planning and adaptation could be enhanced by strengthening partnerships across the wider Caribbean region and the US mainland (*medium confidence*).

Small islands provide a special case for development and adaptation due to their geographic isolation, complex geographies, diverse cultures, and unique natural resources, compounded by challenges such as their small economies, limited human resources, and costs of utility provision and services.[247,248] Sound policies and institutional capacity are fundamental to effective risk-reduction and disaster response and recovery, as well as the ability to seize current and emerging opportunities for adaptation planning and implementation.

For PR and the USVI, significant financial resources could be made accessible for climate adaptation and comprehensive disaster management, such as through disaster recovery funds, the Community Development Block Grant Mitigation (CDBG-MIT) program, and other federal and nongovernmental organization donors. However, effective adaptation planning is impeded by limited uptake of climate change information in decision-making,[249] weak linkages between programs,[250,251] and insufficient institutional capacity for prioritizing initiatives and designing linked operational systems across multiple organizations.[168,252,253] In addition, adaptation and recovery could be made more efficient and effective by allocating funds that account for social vulnerability metrics.[254]

Policy for climate change planning and adaptation in the US Caribbean has advanced slowly in recent years, as evidenced by the Puerto Rico Climate Change Mitigation, Adaptation, and Resilience Act[255] and Executive Order No. 474-2015: Preparing the Virgin Islands of the United States for Adapting to the Impacts of Climate Change.[256] The Puerto Rico law that created the Expert Advisory Committee on Climate Change mandates that the government allocate funds for its operation and develop a climate change mitigation, adaptation, and resilience plan. Many community-based organizations have also taken action to advance social transformation, climate adaptation, and sustainable development.[257,258,259,260] Organizations in PR include Casa Pueblo (energy); Vieques Love (disaster preparedness, resilience, and capacity building); Mujeres de Islas (sustainable development); Vida Marina (dune restoration); Protectores de Cuenca (watershed restoration); Corporación de Servicios de Salud Primaria y Desarrollo Socioeconómico El Otoao (socioeconomic development and public health); and El Josco Bravo (agriculture). Organizations in the USVI that have taken action on climate change include the University of the Virgin Islands Caribbean Exploratory Research Center (climate change and health), St. Thomas East End Medical Center Corporation (education program on climate change and health), and Foundation for Development Planning Inc. (advocacy on climate change and disaster risk-reduction and participation in public policy process on climate change). Self-organization has also enhanced community trust and cohesiveness.[13]

In the USVI, the US Department of the Interior funded a climate change initiative in 2016 that produced a vulnerability and risk assessment report.[261] The Caribbean Climate Hub and a limited number of civil society organizations supported the initiative. However, there is currently no climate change adaptation program in the USVI, and the inadequate uptake of climate change information for decision-making identified in 2016[249] is still reflected in current public sector policies and programs in both the USVI and PR.[262]

Challenges and Opportunities

Advances in climate adaptation planning and implementation by individuals, communities, and public, private, and civil society organizations are constrained by shifts in demographics, fiscal and socioeconomic conditions and capacities, and high levels of risk exposure in the region (KM 31.2).

In PR and the USVI, vulnerable populations are located in sites exposed to high climatic risk.[20,263] Social determinants of vulnerability include economic instability and limited access to education and healthcare services.[254,264,265,266] This vulnerability amplifies the effects of disasters and undermines the ability to prepare, respond, recover, and adapt.[168,254,267,268]

Between 2000 and 2019, PR was among the territories and countries most affected by extreme weather–related events, and between 2010 and 2020, it registered the highest number of new displacements in the Caribbean,[269,270] largely because its residents are US citizens and can move to the continental US without restrictions.[271]

The US Caribbean experiences both in- and out-migration, which should be considered in planning and adaptation, as migrants require permanent or temporary shelter and essential services.[272] Progress in policy, programs, and implementation has been made, but the dynamics of intraregional migration are not fully understood or addressed.[270]

Decision-making processes and program delivery mechanisms typically involve multiple institutions, including civil society organizations. However, these public and private organizations often work in silos or with limited coordination or collaboration. The effectiveness of these mixed-delivery systems would be significantly improved through enhancements to coordination mechanisms, improved institutional processes, and increased investment in human resources to understand and manage the connected processes and systems (Ch. 31).[42,251,262,273,274] Similarly, overcoming the limitations in the institutional capacity to develop and manage federal grants will help advance adaptation actions in PR and the USVI.[275]

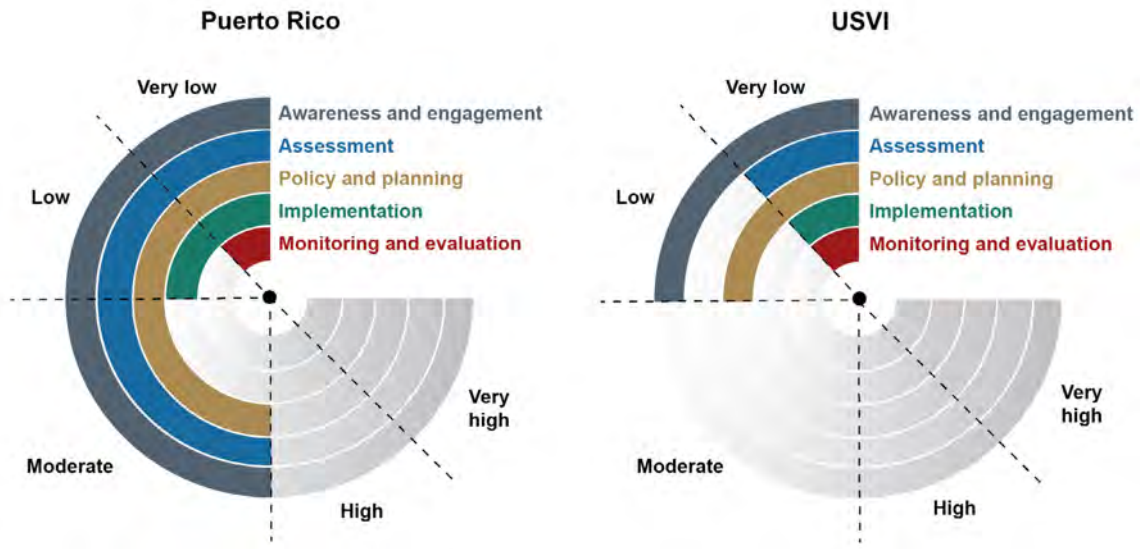
The physical separation of the US Caribbean from the mainland makes disaster response more complex and difficult.[253] Recent reports on the response to Hurricanes Irma and Maria highlight the need for improved planning processes and delivery systems in the relevant federal agencies.[276,277] Ensuring that federal policies and programs are appropriate to local physical conditions and institutional environments and include flexibility to account for future shocks and disturbances could improve disaster response and recovery, as well as climate adaptation action. Policies and program designs that incorporate sustainable land management approaches could reduce vulnerabilities associated with the location of infrastructure and housing in coastal areas and flood zones, water and food insecurity, and degradation of ecological systems. Enhanced alignment of federal and local programs could improve project, program, and development outcomes in the two territories. The government has a fundamental role in creating an appropriate enabling environment for sustainable development—that is, the social ecosystem created by the interplay of policies, laws, institutions, and processes that influence the development of a country. Therefore, ongoing investment in the capacity of government could help ensure that it has the competence to formulate and deliver public policy, maintain significant decision-making capabilities, maintain appropriate and effective governing systems, and develop resilience to shocks.[199,252,278,279,280,281,282]

Current risk-mitigation and emergency response programs focus predominantly on preparedness, response, and recovery—only three of the four phases of a comprehensive disaster management program. The fourth phase is prevention and mitigation, and it is in this phase that economic, legal, sociopolitical, institutional, and other measures are integrated to reduce vulnerability and strengthen resilience.[283,284] In this context, building resilience to disasters and climate change could be enhanced by improving institutional capacity for risk assessment and management.

Both PR Act 33-2019 and USVI Executive Order 474-2015 provide governance frameworks that facilitate coordinated planning and participatory decision-making that involve the public, private, and civil society sectors and the general public. Current federal funding streams available to the territories under the CDBG-MIT program also present an opportunity to advance disaster risk-reduction strategies by focusing more on mitigation and prevention. Modification of the current plans for the USVI and Puerto Rico would make better use of this opportunity.[285]

In the USVI and PR, varying levels of progress have been made across the key elements of climate adaptation (Figure 23.12). This progress reflects the reality that adaptation is an ongoing process that requires evolving governance arrangements to facilitate engagement by all of society.

Status of Adaptation Action



Adaptation action in Puerto Rico and the US Virgin Islands reflects different starting times and available capacity.

Figure 23.12. The figure illustrates progress in adaptation action in Puerto Rico and the US Virgin Islands. The colored bars in the charts show the level of progress for each key element of climate adaptation. Adaptation is presented as a continuous process in which multiple elements may overlap or advance simultaneously. Accelerating adaptation action in both territories would reduce risk and enhance resilience. Figure credit: NOAA/Lynker and Foundation for Development Planning Inc. See figure metadata for additional contributors.

Monitoring, research, and action on regional changes to weather systems, ocean health, and terrestrial and coastal ecosystems may be beyond the financial means of individual island states and territories, underscoring the need for pooling of resources and experiences across the region. Many formal and nonformal relationships exist between institutions, governments, and professional associations in the US Caribbean and other Caribbean countries, which provide opportunities for improving climate adaptation actions through stronger regional collaboration.

Traceable Accounts

Process Description

This chapter was written by a multidisciplinary team of 22 authors that was built in August and September 2021 according to inclusive criteria that sought a diversity of voices by gender, ethnicity, discipline, career stage, knowledge, and geography. Approximately half of the authors work mainly in Puerto Rico (PR), 35% in both US territories, and 15% in the US Virgin Islands (USVI). Sixty percent of authors represent academia, followed by the public sector (about 20%), nongovernmental organizations, and the private sector. The authors are Hispanic- or Latino-Spanish speakers, Afro-Caribbean Black English speakers, and White alone or combined with other races.

Starting in September 2021, the team held weekly all-author meetings to build relationships and capacity. The authors worked in distributed writing teams, each responsible for leading the narrative in each topic and providing evidence supported with literature. On January 19, 2022, the Caribbean chapter hosted a public engagement workshop with 90 participants. Since January 2022, the team continued holding weekly meetings where programmatic and technical issues were discussed. Each Key Message writing team and the chapter lead held weekly meetings to discuss thematic issues, figure development, and more in-depth discussions related to each Key Message.

Key Message 23.1

Climate-Driven Extreme Events Exacerbate Inequities and Impact Human Health and Well-Being

Description of Evidence Base

This topic combines the most recent peer-reviewed information and gray literature on assessment of climate change impacts on the health of people in the US Caribbean. The peer-reviewed literature came from a range of sources.[14,42,50,52,56,59,60,61,62,63,64,80,81,210] The gray literature and reports sourced information from local databases in US Caribbean government agencies and surveys, as well as from databases and other reports.[53,54,67,286] US Census reports lay the foundation for the challenges with descriptions of high levels of poverty and incomes below the US median in both Puerto Rico and the USVI. The literature describing the background information regarding the history of US Caribbean populations being disadvantaged and underserved is documented for the USVI in the needs assessment conducted by Michael et al. (2019)[42] following the 2017 hurricanes; it also provides a combination of local and federal data and information indicating challenges with access to and the extent of services to significant portions of the population before and after the hurricanes. Similar assessments for Puerto Rico have been done by Maldonado et al. (2021)[287] (residential security and community relocation), Seara et al. (2020)[288] (fishing community perception of climate impacts), and Boger et al. (2019)[44] (cultural heritage and traditional knowledge). The relevance of the links between cultural and traditional resources and well-being of people are reported in Boger et al. (2019);[44] Dawson (2013);[289] Finneran (2017);[290] Kohler and Rockman (2020);[291] Perdikaris et al. (2021);[292] and Rockman and Hritz (2020).[293]

There is strong evidence[23,81] in Puerto Rico that extreme heat episodes and extreme rainfall events are increasing in frequency, intensity, and duration, posing the threat of increased incidence of heat-related illness and death, but such evidence is more limited for the USVI at this time. Data on underestimation of

mortality was presented for Puerto Rico specifically in Santos-Burgoa et al. (2018)[56] and in NCHS (2019)[294] in the context of the COVID-19 pandemic. The quantification for USVI is not available for the period after Hurricane Maria.

Major Uncertainties and Research Gaps

Post-disaster settings present opportunities for researchers and for developers, often to the detriment of local or impacted communities.[292,295] Louis-Charles et al. (2020)[36] call for the need to pay closer attention to the ethics of engagement between, on the one hand, external researchers, agencies, and investment interests, and, on the other, local communities in the Caribbean. Although there have been popular claims calling out the damages of post-disaster gentrification in the media, social media, and popular music, not much research has been conducted on how disaster capitalism exacerbates injustices and cultural erasure in Puerto Rico and the USVI. Elders and Traditional Knowledge highlight concerns with rates of migration of youth and disarticulation of traditional communities that still would benefit from further research.[296]

While research on aerosol and aeroallergen distribution and health impacts has been conducted in Puerto Rico, this association has not yet been quantified in the USVI.

Reports[42,51] and peer-reviewed literature describe impacts of extreme weather and the efforts or needs to mitigate or adapt activities in both Puerto Rico and the USVI.[297] Strengthened education and adaptation outreach efforts could help address issues with behavioral health, noncommunicable disease burdens, and other challenges.

The impact of sargassum algal mats reaching the coasts of the US territories is uncertain. Evidence from other Caribbean islands suggests that this phenomenon will contribute to worsening air quality, ecosystem health, and public health in coastal areas. There are some initial initiatives on an early warning system for Saharan dust, extreme heat, and public health, yet preparedness of the public health sector to mitigate illnesses is still low (and lower in the USVI than in PR). There are uncertainties related to Saharan dust clouds and how climate change will affect seasonality, patterns, concentration, and dust distribution. There are still uncertainties as to why excess mortality happens for extended periods after a natural event; the understanding of these mechanisms requires the identification of the cause-specific mortality and the different conditions leading to death, including infrastructure, critical building capacity, housing, and living conditions. Such an approach is currently being advanced in a project led by the National Institute of Standards and Technology.[298]

Description of Confidence and Likelihood

There is *high confidence* that climate-related extreme weather events contribute to loss of quality of life and well-being in the US Caribbean. Long histories of colonization, generational trauma, and systemic inequality shape the ability of the US Caribbean peoples to maintain health, quality of life, and overall individual and social well-being (*high confidence*). The level of local and federal research and reports following Hurricanes Irma and Maria in 2017 included information on trends and also identified significant changes and challenges with general health, support services, mental health and well-being in general. In addition, it was noted that the conditions that supported the poor outcomes are major challenges for communities in both PR and the USVI. More frequent heat episodes and powerful hurricanes are expected to increase in the region due to human-induced climate change, affecting public health unless clear and urgent adaptation measures take place (*high confidence*). Climate conditions are favorable for vector-borne diseases (e.g., dengue, Zika, and chikungunya) and human zoonotic diseases (e.g., leptospirosis) in the US Caribbean (*high confidence*). However, many behavioral factors play a confounding and important role (e.g., life-concurrent events, social distancing, age, exposure) in the spread of these diseases. There is *high confidence* in the data and methods in the estimation of the excess mortality in Puerto Rico from Hurricane Maria, and such estimates are now in the official NOAA reports.[299]

Key Message 23.2

Ecology and Biodiversity Are Unique and Vulnerable

Description of Evidence Base

This topic reviews and synthesizes the most up-to-date assessments of climate change impacts on biodiversity, ecosystems, and ecosystem services in the US Caribbean region. The review included gray literature alongside peer-reviewed literature. The peer-reviewed literature considered strong resources from academic and scholarly journals such as the *Journal of Ecology*; *Biological Conservation*; *American Journal of Marine Science*; *Sustainability Science*; *Ecological Indicators*; *Estuarine, Coastal and Shelf Science*; and *Ecosystem Consequences of Soil Warming*. The gray literature included reports, documents, and white papers from federal and local agencies (USDA, USGS, FEMA, US Global Change Research Program, Puerto Rico Department of Natural and Environmental Resources), government entities (Puerto Rico and US Virgin Islands Taskforce), academia (University of Puerto Rico, University of the Virgin Islands), and nonprofit organizations.

The preliminary literature review established and confirmed the observed ecosystem- and biodiversity-level changes in response to climate change due to direct impacts from climate drivers[20,118,123,125,130,136] and the lack of effective adaptation strategies, policies, and measures.[141] Most of the comprehensive assessments reviewed illustrated the rapid changes of habitats, species, and abundance.[131]

Major Uncertainties and Research Gaps

Both territories experience weather- and climate change–related hazards such as drought, sea level rise, coastal flooding, and erosion. However, the amount of climate research, observations, assessments, and modeling (prediction) are greater in PR than in the USVI. It would be necessary to gather knowledge and information from local agencies, institutions, community-based organizations, and even unpublished information to address existing and pressing gaps in the understanding of climate impacts on biodiversity and ecosystems in the USVI.

Description of Confidence and Likelihood

There is *high confidence* that the synergistic effects of climate and non-climate stressors are impacting ecosystem goods and services, given the expanding literature with regional examples of these changes. As documented in federal, regional, and local climate change assessment reports, climate and non-climate stressors are *very likely* to persist and become more severe, further accelerating ecosystem degradation and aggravating their service efficiency. These assessment reports also highlight the dependence of the US Caribbean residents on ecosystem services for their well-being and livelihood (*high confidence*), hence the need to safeguard these services. Based on a broad range of evidence, there is *high confidence* that maintaining ecosystem functionality will require integrating effective local-level adaptation and mitigation strategies. However, given the lack of literature on implemented adaptation strategies, there is *medium confidence* that local-level adaptation and mitigation strategies could reduce and manage the risks of climate change on coastal and terrestrial ecosystems.

Key Message 23.3

Climate Change Threatens Water and Food Security

Description of Evidence Base

The discussion of the vulnerability of the US Caribbean food and water systems to climate change is based on observations within the islands and projected changes in the regional and global climate.[10,12,20,21,23,24,25] Localized threats to water and food security include changes in drought intensity, frequency, or duration[20,21] and tropical cyclone rainfall rates and intensity.[24] There is mounting evidence of the impact of climate-related extreme events on the food and water system based on measurements, local knowledge, and published and gray literature.[149,152,168,200,300] There is strong evidence that both hurricanes and drought are major issues for island food and water systems, as illustrated by the impacts of Hurricanes Irma, Maria, and Fiona[168] and the 2014–2016 drought.[300] The direct and cascading impacts of these climate stressors with additional compounding problems, especially sea level rise, are a concern for food and water systems.[165] The literature on direct climate impacts to certain sectors such as crops and livestock is widely available[156,185] for Puerto Rico but is limited for the USVI. The evidence is limited when specifically considering island freshwater and food availability and is mostly available through evidence captured by the drought information system reports.[301] There are no systematic studies that quantify the cascading and compounding impacts of these hazards.

Major Uncertainties and Research Gaps

The lack of availability of high-resolution climate change projections that better resolve the island climates is a major research gap for understanding plausible future changes in the island climates. Major uncertainties exist with respect to the role of the island terrain and land-use and land-cover change as the climate warms.[21] This research gap is larger for the USVI than for PR. Another modeling challenge and research gap is how future tropical cyclones may interact with small islands like PR and the USVI, especially as rainfall intensity increases in a warmer climate, with cascading impacts on food and water systems. The association between natural hazards and decreased food security or diet diversity in PR and the USVI is another research gap.[302] For the USVI, there is a noted gap of statistics and scientific impact studies on food production and water use. An area of research not discussed is the impact of climate change and major storms on Puerto Rico and the USVI. While there are some reports that document the impact of climate change on fisheries within the Caribbean basin, there are fewer studies that assess the impacts for Puerto Rico and the USVI.[303,304] The role of community-based efforts for mitigating food and water insecurity, as well as the importance of local and Indigenous knowledge to these ends (KMs 30.1, 30.5), has been poorly researched in the US Caribbean and deserves further attention. More information is needed to better assess the impact and response to extreme climate events.[305] Finally, there are research gaps in the compounding and cascading impacts generated by climate change in both Puerto Rico and the USVI.[168]

Description of Confidence and Likelihood

In the first statement of the Key Message, there is *high confidence* that the US Caribbean food and water systems will become more vulnerable as the climate warms, in part because extreme meteorological events like hurricanes and droughts are *likely* to become stronger and more severe in the future. There is *high confidence* that climate change at both global and regional scales is important because the islands are heavily reliant on imported foods. However, climate change projections at the scale of the islands are limited to a few studies, allowing *medium confidence* in predictions of local direct impacts of climate change on freshwater availability for the region. While improved knowledge will enhance adaptation, the authors have *medium confidence* because the adaptation process also relies on social and economic changes. The evidence base was not sufficient to determine quantitative probabilities for the second through the fourth statements in this Key Message; thus, no likelihood is specified.

Key Message 23.4

Infrastructure and Energy Are Vulnerable, but Decentralization Could Improve Resilience

Description of Evidence Base

The vulnerability of US Caribbean infrastructure systems to climate change is based on observations of impacts of recent climatic events within the islands and projected changes in the regional and global climate. The evidence to support current vulnerability of systems and future climate vulnerability is mostly based on documents from the gray literature, including reports from federal agencies and/or sponsored by federal or territorial agencies[199,200,204,230] following Hurricanes Irma and Maria. The published literature and reports are not as rich as for locations in the continental US. The description of the need for a paradigm change in the governance of infrastructure systems is based on a number of peer-reviewed journal articles describing observations of the limits of current governance systems, as well as more academic journal articles addressing best practices for building resilient infrastructure systems. There is very little published literature on the effects of governance on the ability to adapt, especially in the US Caribbean.

Major Uncertainties and Research Gaps

The availability of more structural and system operation assessments of the vulnerability of infrastructure systems to flood and wind events is a major research gap, because most assessments are made by looking at the presence or absence of a system component in a flood zone. Often it is unclear whether the system component can be accessed or operated, or even whether it may have been rendered unsafe by previous mitigation activities that took place. Another gap is the lack of availability of public geodatabases of infrastructure systems. The region is also missing flood maps that take into account future climates. Furthermore, understanding the effectiveness and feasibility of decentralized governance systems for critical infrastructure is a major research gap and need, as much of the current literature demonstrates the limits of centralized systems in the Caribbean. Finally, the lack of easily accessible data on water and power consumption, traffic patterns, and other ways that humans use infrastructure systems is a major data gap that needs to be filled so that adaptation strategies can be developed to mitigate against any disruption in the delivery of services.

Description of Confidence and Likelihood

Based on the level of damage incurred during Hurricanes Irma and Maria (2017) and Hurricane Fiona (2022), as well as the post-2017 hurricane reports published by the government and federal agencies, there is *high confidence* that infrastructure systems in the US Caribbean are suffering from a lack of maintenance and investment and that climate change has created profound risks for the US Caribbean's critical infrastructure, especially as extreme meteorological events become more *likely* in the future. There is *high confidence* that dependence on fossil fuel imports increases energy insecurity, based on numerous reports from the gray literature and the recent fiscal difficulties experienced by the public utilities in both Puerto Rico and the USVI.

Given the lack of stability of the public utilities, as described in government and federal agency reports, and given the relative lack of long-term data on the effectiveness of solar electric systems as an alternative to centralized systems to provide power to communities during and outside of disasters, there is *medium confidence* that decentralization of system production and distribution, and *medium confidence* that decarbonization and shared governance, will *likely* help limit residents' vulnerability to health and other risks associated with the loss of essential services programs.

Key Message 23.5

Adaptation Effectiveness Increases When Coupled with Strategic Governance and Planning

Description of Evidence Base

The evidence to support the Key Message consists of articles in peer-reviewed journals, research publications by universities, technical papers, assessment reports produced by or on behalf of the federal and territorial governments, executive orders and legislation passed by the territorial governments, and technical reports by Caribbean and global intergovernmental organizations.

The peer-reviewed journals were classified with impact factors that range from 3.20 to 9.5, indicating that the journals are trustworthy. The documents prepared or funded by federal and territorial governments underpin the conclusions regarding challenges of various levels of government for effective planning and adaptation.[148,249,252,253,276,277,279] Literature that supports the conclusions regarding effective adaptation action through improved governance arrangements and coproduction with community organizations includes McGinley et al (2022),[168] Filantropia Puerto Rico Inc. (2022),[258] and Towe et al. (2020).[262] The gray literature also includes publications by research institutions such as the National Institute of Building Sciences, the International Council for Local Environmental Initiatives–Local Governments for Sustainability USA, the University of the Virgin Islands, and the University of Colorado.

Since the publication of the Fourth National Climate Assessment in 2018, climate adaptation action is increasingly being informed by high-quality data, policies, laws, white papers, and technical reports prepared by the governments of the two territories, Puerto Rico's Expert Advisory Committee on Climate Change, the Puerto Rico Climate Change Council, the Governors' Institute on Community Design, academia, scientists, and community-based organizations.

Major Uncertainties and Research Gaps

A large body of literature is available globally and for the wider Caribbean on the benefits of local adaptation through coproduction. For the US Caribbean, although there are participatory efforts, mostly from the nonprofit sector and many supported by academia, the published literature is sparse. As such, additional research and evaluation on the capacity requirements and design for collective action would enhance implementation.

Description of Confidence and Likelihood

Statements about the challenges of climate adaptation in the US Caribbean due to multiple interacting factors—including high risk exposure, limited or misaligned funding, insufficient institutional and organizational capacity, and siloed approaches to risk reduction and resilience—are based on extensive analysis of peer-reviewed papers; federal, regional, and local technical reports; and the onsite experience of the multidisciplinary, multisectoral team of 22 authors of this chapter. Authors had the opportunity to deal with, study, and/or assess these diverse interacting factors that are related to climate adaptation in the US Caribbean from diverse points of view. As a result, authors have *high confidence* in the first statement of the Key Message.

On-site experience, data, and numerous studies with consistent findings support the idea that US Caribbean adaptation could be enhanced through co-development and integration of robust global, regional, and local climate science and risk-based knowledge into planning and implementation, as well as improved governance, resulting in *high confidence* in the second part of the Key Message.

Based on a smaller number of studies but further deliberation among our author team, the statements about how US Caribbean capabilities in planning and adaptation can be enhanced by strengthening partnerships across the wider Caribbean region and the US mainland is assigned *medium confidence*.

Introduction

The Midwest is diverse in landscapes, people, and culture. The region covers more than 328 million acres, with approximately 284 million acres covered by croplands and forests or designated as public land. It sustains vital ecosystems and wildlife and provides refuge and recreation for its residents, including 35 Federally Recognized Tribes and numerous other state-recognized and non-recognized Tribes. More than 40,000 natural lakes and thousands more human-made reservoirs and ponds dot the landscape. The Midwest borders four of the five Great Lakes; together, the five Great Lakes contain approximately 21% of the world's surface freshwater supply, and about 10% of the US population lives within the Great Lakes basin. There are more than 500,000 miles of rivers and streams flowing through the region, including the Mississippi, Missouri, and Ohio Rivers—critical lifelines enabling the exchange of goods and services throughout the country. The Midwest is linked by more than 2 million miles of roads, 160,000 bridges, 34,000 rail miles, and 3,000 airports. It has 41 cities with at least 100,000 residents, including 5 of the 30 most populated cities in the United States. All of the Midwest states except Illinois have lower urban populations than the national average, and 74.3% of the Midwest population lives in urban areas.[1]

The climate of the Midwest has warmed since the first half of the 20th century, and annual precipitation has increased (Figure 2.4). Sub-annual changes, such as the recent lack of warming during summer and rapid oscillations between extreme wet and dry periods (Figure 24.1), increase the complexity and uncertainty of future impacts. Nonetheless, these changes have impacted agriculture (KM 24.1), natural resources (KM 24.2), health and well-being (KM 24.3), the built environment and transportation (KM 24.4), and water quality and quantity (KM 24.5) in societally important and interconnected ways. Increasing temperatures and oscillations between extreme droughts and floods threaten field crops, specialty crops, and animal production across the Midwest,[2,3] which have direct and inequitable impacts on global food supply and security (KM 11.2). These rapid oscillations in hydrology will continue to transform aquatic and terrestrial ecosystems, many of which strongly influence individual and community health and the built environment. These observed and projected changes greatly limit access to natural areas, including those intimately tied to winter ice.[4] Not only does climate change threaten recreation and the economy of this region, but it also disrupts important identity connections between Indigenous Peoples and their ancestral lands (KM 16.1).[5] Individual and community health is at risk, with cascading impacts on social and cultural connections that highlight inequitable health disparities tied to race, ethnicity, age, and income (KMs 14.1, 15.2). Aging infrastructure creates uncertainty in the ability to meet current and future energy needs and withstand increasing volumes of water. Although rural landscapes dominate the Midwest, urban centers concentrate climate risks and socioeconomic inequities (KM 12.2). NOAA's Billion-Dollar Weather and Climate Disasters report (Figure 2.6) does not fully account for the burden felt by low-income populations of urban centers due to chronic, smaller-scale flooding events. Finally, projected increases in temperature and precipitation variability threaten the ability to maintain water quality and manage the Mississippi, Missouri, and Ohio Rivers in ways that maintain the flow of goods and services throughout the region and the country. The Great Lakes indicators, from fish consumption to invasive species, show diverse conditions. Many of the complex interactions between climate changes, the lakes, and their surrounding land and populations raise uncertainty in long-term projections of lake levels and trends in environmental and ecosystem metrics (Table 24.1),[6] and this uncertainty has important implications for international collaboration and adaptive management in the Great Lakes (Box 4.3).

Despite these many risks to the economy and identity of the Midwest, people are responding in ways that offer hope for the future. Researchers are identifying climate-smart agriculture practices that could help boost profitability and improve economic and environmental sustainability (Figure 24.4). There is growing recognition that undeveloped natural lands provide economic and social benefits by contributing to climate mitigation and adaptation (providing nature-based solutions through effective resource management)

and that collaboration with Tribes on land issues improves climate outcomes for all residents. Within communities, people are engaging with one another to identify solutions to address structural, institutional, and systemic factors that contribute to inequities and climate injustice. Researchers and practitioners are collaborating to build transportation and energy networks that are resilient to climate change while also maintaining social cohesion in the process. For example, experimental port management in the Great Lakes is assuming the role of ecological restoration, which also improves the social health of the region (Figure 24.9). Communities like Milwaukee have developed public–private partnerships and increased green stormwater infrastructure. Finally, federal partners are working with state and local agencies to build tools and approaches to address climate-related challenges such as drought and harmful algal blooms.

Key Message 24.1

Climate-Smart Practices May Offset Complex Climate Interactions in Agriculture

Crop production is projected to change in complex ways (*likely*, *medium confidence*) due to increasing extreme precipitation events and transitions between wet and dry conditions (*likely*, *medium confidence*), as well as intensification of crop water loss (*likely*, *low confidence*). Changes in precipitation extremes, timing of snowmelt, and early-spring rainfall are expected to pose greater challenges for crop and animal agriculture, including increased pest and disease transmission, muddier pastures, and further degradation of water quality (*likely*, *high confidence*). Climate-smart agriculture and other adaptation techniques provide a potential path toward environmental and economic sustainability (*medium confidence*).

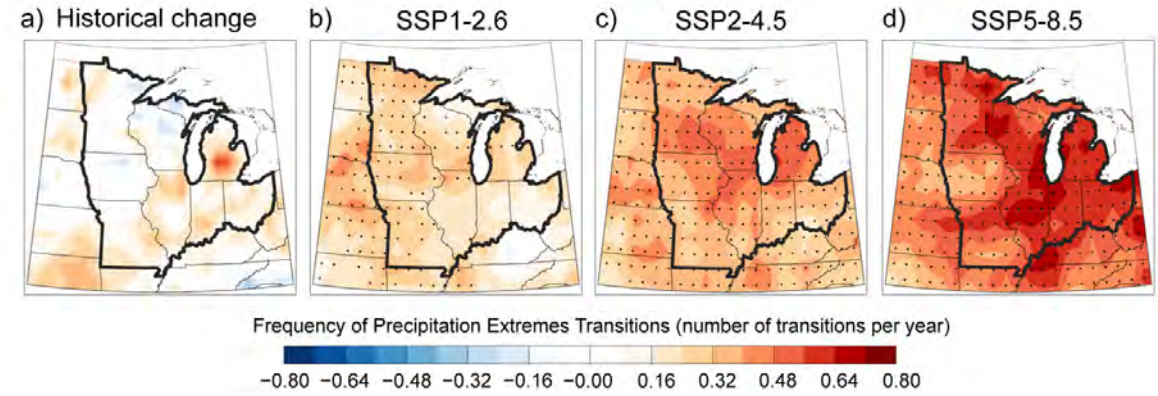
Risk

The Midwest is among the most intensive agricultural regions globally, producing more than 30% and 32% of the world's corn and soybeans, respectively; numerous specialty crops; and livestock in concentrated animal operations.[7,8] Climate change is already affecting Midwest agriculture, and projected climate changes increase these risks.

Impacts

Annual precipitation increased by 5%–15% across much of the Midwest during 1992–2021 (compared to the 1901–1960 average), with some areas experiencing reduced precipitation during summer (Figure 2.4).[9,10,11,12] These trends, particularly across the north-central region of the US, have been partly attributable to human influence.[13,14] Projections (under low [RCP2.6] to very high [RCP8.5] scenarios) suggest precipitation increases across the Midwest ranging from 8% to 20% by midcentury relative to the previous five decades, with individual model uncertainty regarding the degree, direction (wetter or drier), and regional spatial characteristics (KM 3.3).[10,12,15,16,17] Rapid transitions between precipitation extremes are expected to increase across all of the Midwest by late century (2071–2100) compared to historical conditions (Figure 24.1).[17,18] Amplified precipitation variability and more frequent wet–dry transitions increase the risks of transient drought and harm to crops, requiring changes in management systems to maintain food security.[19,20,21]

Change in Frequency of Transitions Between 1-Month Precipitation Extremes



The frequency of wet–dry and dry-wet transitions across the Midwest is projected to increase by late century (2071–2100).

Figure 24.1. Transitions between wet and dry periods are expected to become more frequent across the Midwest. Observed changes in transition frequency (from wet to dry or dry to wet) are based on the Standardized Precipitation Index (SPI), represented by the difference between the periods 1951–1980 and 1981–2010 (historical change, panel **a**). SPI is a common statistical index that quantifies the relative intensity of drought or wetness, and monthly SPI values are utilized to show transitions over short periods. Projected changes in transition frequency under low (SSP1-2.6; **b**), intermediate (SSP2-4.5; **c**), and very high (SSP5-8.5; **d**) scenarios are represented by the difference between the periods 2071–2100 and 1981–2010. The black boundary outlines the Midwest region. Black dots indicate grid cells where the model-projected transition frequency is significantly different from the historical climatology. Adapted from Chen and Ford 2023[18] [CC BY 4.0].

Although average corn and soybean yields increased in recent decades in the Midwest,[22] both excessive moisture (flooding) and extreme droughts significantly decreased corn yields in some locations and years by up to 37%.[2,23] Excessive spring moisture has delayed corn planting by up to a month,[24] while episodic droughts have reduced yields[2] despite increasing annual rainfall.[25]

Future projections suggest further changes in seasonality and increases in variability. Earlier snowmelt is expected to increase daily maximum spring streamflow.[26] Intermediate (RCP4.5) to very high (RCP8.5) scenarios show both an increase in the frequency of wet springs and decreasing summer precipitation and drier soils.[15,27,28] More intense precipitation during the early spring, when soils are largely uncovered and wetter, increases soil erosion[3] and leaching of nitrogen fertilizer.[10] Additionally, water quality concerns (KM 24.5) are compounded due to more frequent spring manure storage overflow and increased pressure on farmers to spread manure early.

Temperature increases directly affect crop development and physiology[29,30,31] and lead to increases in evapotranspiration and stress during dry conditions.[32] While daily minimum temperatures have increased, daytime maximum (summer) temperatures have cooled in some areas of the Midwest (1991–2021 compared to 1901–1960; see Figure 2.4). This is an important trend for the Midwest and differs from that of other regions (Figure 3.11). Often referred to as the "warming hole,"[33] this trend may be partly explained by the expansion of croplands and increased transpiration over parts of the Midwest and Northern Great Plains (KM 25.2).[34,35,36,37,38] Increased transpiration may have also induced observed summer rainfall increases over parts of the region.[34] These changes may have contributed to improved corn yields.[39,40,41] Projections across a range of scenarios (low [SSP1-2.6] to very high [SSP5-8.5]), however, show that rising temperatures will reduce corn and soybean productivity while maintaining wheat production by the end of the century.[31,42,43] Higher temperatures also increase atmospheric vapor pressure deficit (VPD), enhancing crop water loss. Without expansion of irrigation, projected increases in VPD are expected to limit corn yields.[44,45]

Irrigation in the Midwest affects climate as well. Across the Wisconsin Central Sands region, for instance, irrigated agriculture, compared to rainfed agriculture, has contributed to decreased maximum temperatures, increased minimum temperatures, increased VPD, and decreased evaporative demand.[46] This land-use change/microclimate complexity introduces uncertainty regarding future projections of temperatures and moisture across the Midwest (KM 6.2).

Animal production in the Midwest is also vulnerable to climate change. Increases in winter and spring precipitation and temperature are expected to result in muddier paddocks and pastures, which can decrease fetal growth during late gestation.[47,48,49] Perennial forage crops are under a greater risk of winter injury with climate change because of a greater frequency of above-freezing temperatures during winter.[23] However, there are potential gains in forage productivity with a warmer and wetter climate, longer growing seasons, and higher carbon dioxide concentrations, although with potential declines in quality.[50] Other important livestock impacts include feed shortages, loss of shade structures, nutritional restrictions, disease transmission, and biosecurity concerns (e.g., feral hogs and waterfowl may contaminate existing stocks as they seek higher ground).[51] Increasing temperatures and higher dewpoints place demands on livestock management and housing needs to limit productivity losses or mortality. Heat stress limits livestock production[51,52] and dairy quality.[53] Under intermediate (RCP4.5) and very high (RCP8.5) scenarios, more intense heat abatements (e.g., fans, misting, sprinklers, ventilation) could be necessary to sustain recent production increases,[54] and environmental impacts on dairy production will increase by 2050.[55]

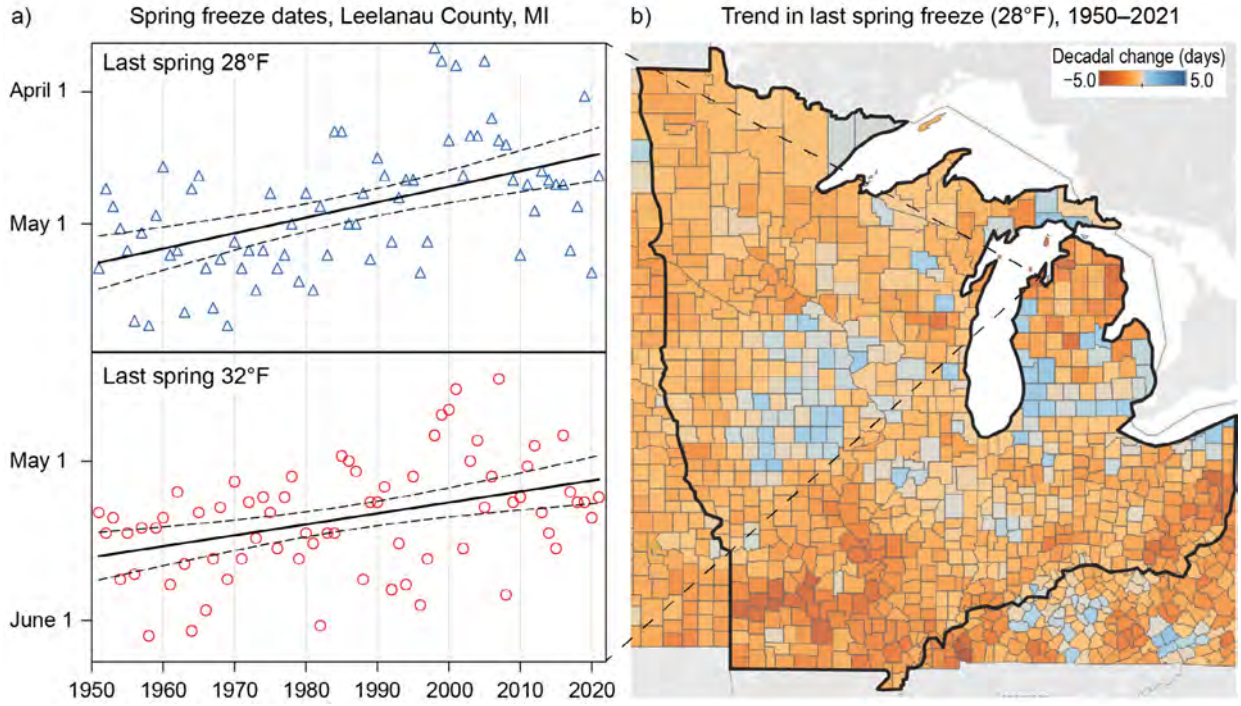
Specialty crops, such as tree fruit and vegetables (e.g., pumpkin and berries), represent a $7.1 billion industry (in 2022 dollars) and have higher potential market values and production-related risks than commodity crops due to their dependence on flavor and appearance.[56,57] Cold injury and damaging frosts during the spring are concerns for both perennial and annual crops (Figure 24.2), and excessive moisture has been associated with significant crop losses for growers throughout the year.[58] Early-season flowering followed by spring freezes (Figure 24.3) has resulted in premature phenological development of tree fruit crops, erratic flowering, and increased risk of freezing injury in April and May.[23,58] Current understanding of future impacts on specialty and horticultural crops across projected climate changes is limited. As temperatures increase, shifts in the timing and growing zones of crops have caused observed pollinator population declines that have translated directly into decreased crop production.[59,60,61] Projected temperature increases suggest continued challenges related to crop growing zones and timing.[62]

Freeze-Damaged Apple Blossoms

Early warmth and flowering followed by freezing temperatures in the spring poses risks to perennial and annual crops.

Figure 24.2. Apple blossoms are damaged by a freeze event on May 9, 2020, in Berrien County, Michigan. Photo credit: ©Dr. Mike Reinke, Michigan State University.

Trends in Last Freeze Dates for Spring



Last spring freezes are occurring earlier over most of the Midwest region.

Figure 24.3. (**a**) Trends (solid black lines) show that the last date in spring when minimum temperatures fall to either 28°F or 32°F in Leelanau County, Michigan, are occurring earlier in the year. For example, the last 28°F temperature commonly occurred after May 1 during the 1950s–1970s, with earlier dates noted since the 1980s. Note the large variability in dates. The statistical significance of the trends (dashed black lines; based on a 95% confidence interval) shows the range of values of the trend line based on the observed dates. In all cases, these confirm there is a trend toward earlier last freeze dates. Panel (**b**) shows change in the number of days per decade of the last spring freeze (28°F) over the period 1950–2021. The black boundary outlines the Midwest region. Orange shading indicates trends toward earlier last spring freeze dates, blue shading indicates trends towards later last spring freeze dates, and gray shading indicates no trend. Adapted with permission from the Midwestern Regional Climate Center's Freeze Date Tool (https://mrcc.purdue.edu/freeze/freezedatetool). Map base layer on right is ©Mapbox ©OpenStreetMap.

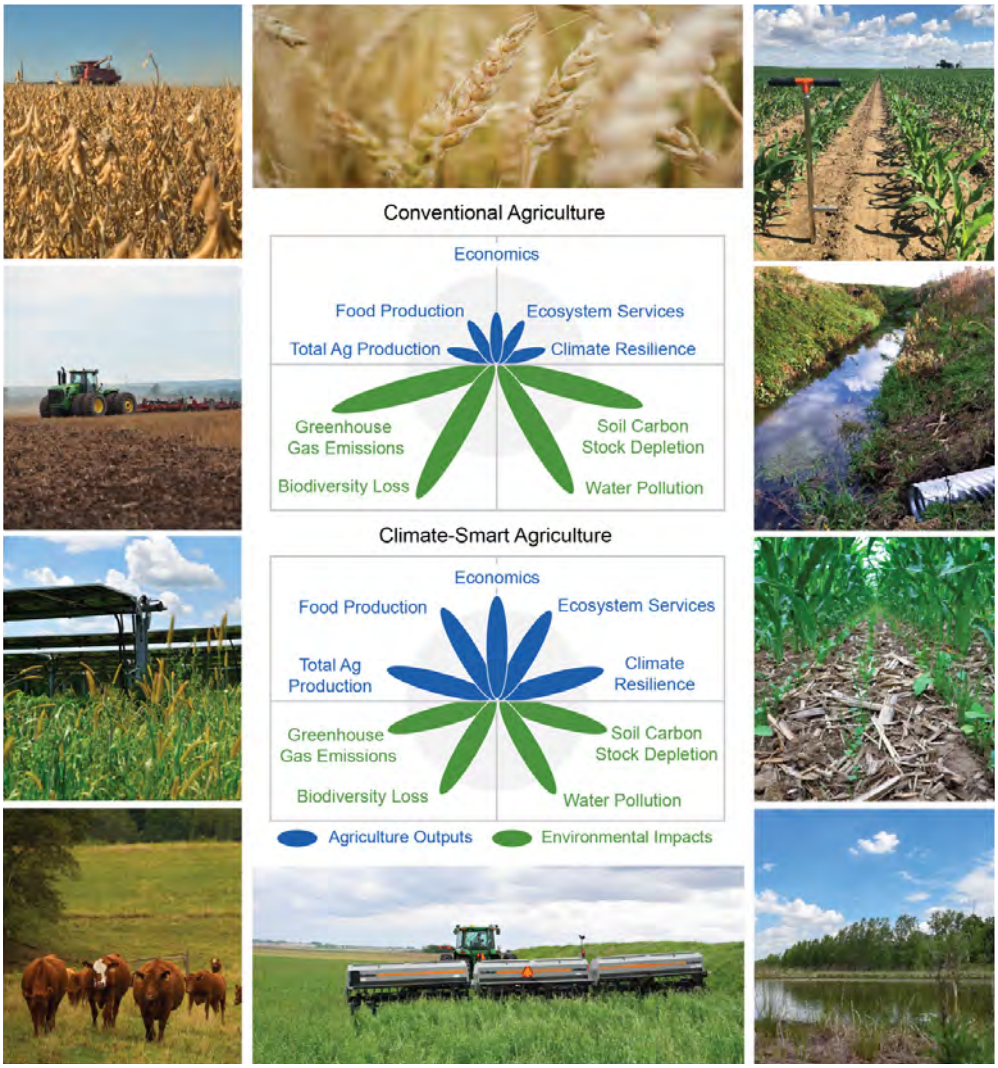
Evidence suggests that pest distributions have shifted northward since the early 20th century, and projections indicate that increasing temperatures will allow pests (e.g., brown marmorated stink bug, corn earworm, Japanese beetle, Mexican bean beetle, and potato leafhopper) to continue expanding northward across the Midwest.[63,64,65,66,67,68] Warming winters lead to insect population expansion throughout the Great Lakes (e.g., Kiefer et al. 2021[69]), while hotter, drier conditions exacerbate yield loss from weed competition.[70] Higher dew points (humidity) increase disease risk for numerous crops, including soybean and apples.[21,71,72]

Most Midwestern row crops are insured, providing growers with some economic security against weather- and climate-related risks.[73] However, US crop insurance losses continue to rise, with an estimated $31.9 billion (in 2022 dollars) attributed to climate change over the last three decades.[74] Drought payments represent the largest percentage of indemnities, although wetness losses are increasing.[75] Evidence suggests an overall decline in drought across the region since 1895;[76] however, an increased occurrence of flash drought (rapid depletion of soil moisture), along with soil degradation[77] and more productive crops,[8] has resulted in moisture stress to crops and native vegetation.[78,79] Damages from droughts and other climate-related financial losses have implications on farmers' mental health as well (KM 24.3).

Climate-Smart Agriculture

According to the United Nations Food and Agriculture Organization, "climate-smart agriculture defines an agriculture that sustainably increases productivity [and] resilience (adaptation), reduces/removes GHGs (mitigation), and enhances the achievement of national food security and development goals."[80] Climate-smart strategies include, but are not limited to, the use of cover crops, reduced- or no-tillage operations, improved nutrient and manure management, wetland and grassland management, agroforestry, bioenergy crops, on-site carbon sequestration, and agrivoltaics (the integration of agricultural production activities and solar energy generation; Figure 24.4). However, there are uncertainties about the climate benefits and detriments of these techniques, particularly in field settings.[81] Cover crops can improve soil health, reduce erosion, and increase soil organic carbon. Five percent of agricultural fields in the Midwest were cover-cropped in 2017, up from 2.6% in 2012.[82] A reduction in yields for cash crops may deter further adoption of cover crops, and recent analyses suggest that non-legume cover crop adoption reduced maize yields by 3.9% to 5.5% in the Midwest.[82,83] Billions of dollars of investment to encourage producers to test various climate-smart practices have come from federal programs and legislation. Precision agriculture, which maximizes the efficiency of input application (e.g., fertilizers, herbicides) allows for homogeneously managed zones within the same field.[84,85] Such approaches have the potential to increase production efficiency; increase resilience to climate-related risks, particularly the loss of nitrogen fertilizer;[86,87] and yield co-benefits for Midwestern ecosystems (KM 24.2). Corn remains the major bioenergy crop in the US, providing ethanol as a biofuel.[88] Whether corn ethanol is a climate-smart practice is heavily debated.[88] Second-generation biofuels from cellulosic biomass feedstocks, including dedicated energy crops (grown specifically for energy and not food production); agricultural crop residues (materials left on land after crop harvest); and wood residues have greater potential to reduce greenhouse gas emissions, with limited adverse impacts on food crop prices and indirect land-use changes compared to corn ethanol.[89,90,91] Additional techniques concerning animal agriculture and greenhouse gas emissions are explored in KM 11.1.

Environmental Impacts from Conventional Versus Climate-Smart Practices



Climate-smart agricultural strategies may have adaptation and mitigation advantages that balance agricultural needs and environmental impacts.

Figure 24.4. The figure shows examples of conventional and climate-smart production methods: (**clockwise from top center**) wheat field in Brownsburg, Indiana; spring corn under fair skies in southwest Ohio with infield soil sampling probe; outlet from water control structure to agricultural drainage ditch; inter-seeded annual ryegrass, clovers, and radishes growing in young corn in Carroll County, Iowa; macrotopograhic feature (ridge and swale) on a wetland restoration easement in Starke County, Indiana; planting green: no-till drilling soybeans into standing cereal rye in Washington County, Iowa; Forage Systems Research Center in Missouri works to improve the quality of forage grass, promotes management-intensive grazing, rotational grazing, cattle management, and the economics of beef and forage; an example of agrivoltaics—combining solar energy production on agricultural production lands; farmer tilling fields: traditional practice to break up soil in preparation for planting; farmer harvesting soybean with combine. The center diagrams compare the agricultural needs (blue ovals and text) with environmental impacts (green ovals and text) for both conventional and climate-smart agriculture. As shown, there is an imbalance between the agricultural needs and environmental impacts of conventional agriculture (represented by the blue and green ovals); whereas climate-smart agriculture may provide more balance between the two. Key Message 24.2

Adaptation May Ease Disruptions to Ecosystems and Their Services

Ecosystems are already being affected by changes in extreme weather and other climate-related changes, with negative impacts on a wide range of species (*likely*, *high confidence*). Increasing incidence of flooding and drought is expected to further alter aquatic ecosystems (*likely*, *medium confidence*), while terrestrial ecosystems are being reshaped by rising temperatures and decreasing snow and ice cover (*very likely*, *high confidence*). Loss of ecosystem services is undermining human well-being, causing the loss of economic, cultural, and health benefits (*medium confidence*). In response, communities are adapting their cultural practices and the ways they manage the landscape, preserving and protecting ecosystems and the services they provide (*low confidence*).

Risk

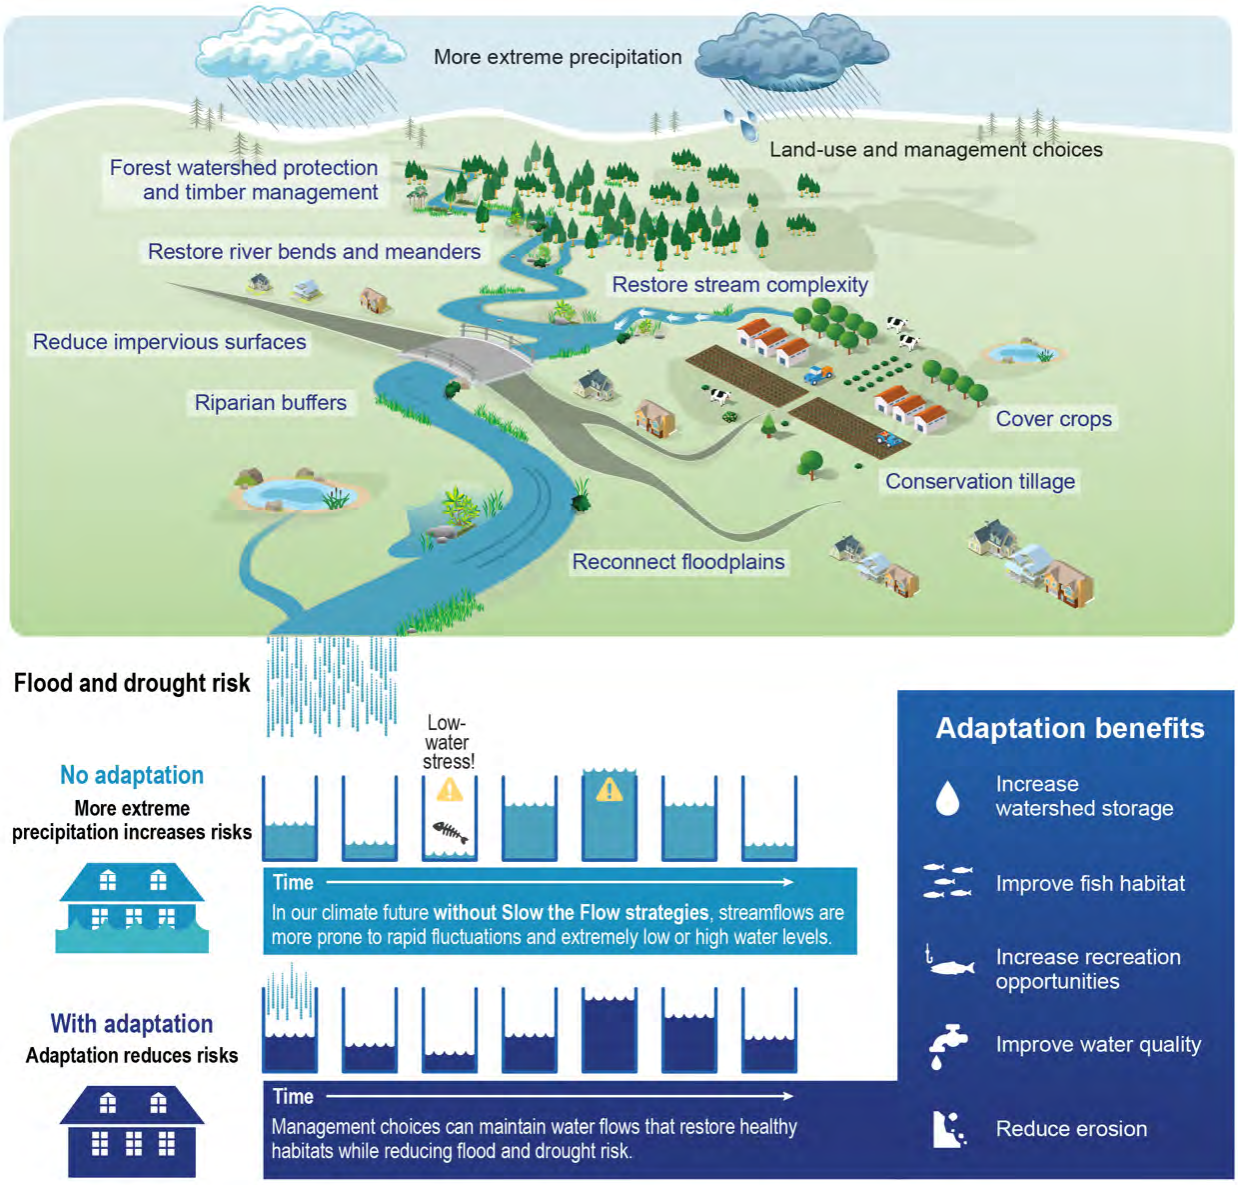
The Midwest is home to many communities and cultures that appreciate and rely on fish, wildlife, waters, and lands. Indigenous communities throughout the Midwest recognize natural resources as persons and extended family (a kin-centric viewpoint) and at times may use terminology such as relatives or beings to refer to them.[93] These relatives support intergenerational continuity, heritage, and spiritual practice. Fishing, hunting, and wildlife viewing are common recreational activities and contribute billions of dollars to the regional economy.[94] Exposure to natural environments enhances human well-being and health,[95] while limited access to natural resources contributes to health inequality.[96]

Impacts

Midwestern aquatic ecosystems are being harmed by rising temperatures and increased precipitation.[97] Climate change intersects with invasive species, land-use change, and human consumption to affect nutrient pollution, water quality, and water levels.[98,99,100,101] For example, invasive species and habitat degradation are negatively affecting walleye growth, survival, and abundance.[98,102,103,104] Mass fish die-offs due to extreme summer heat are projected to double by midcentury (under a very high scenario [RCP8.5]) in northern temperate lakes.[105] Indeed, the Fond du Lac Band of Lake Superior Chippewa has documented an increase in lethal stream temperatures and a decline in brook trout harvest.[5]

Extreme precipitation events degrade riparian ecosystems, erode river and stream banks, disperse contaminants, disrupt plant and animal cycles, and spread invasive species; however, there may be benefits to flooding, including increases in connectivity for aquatic organisms, habitat complexity, and size of the floodplain.[106] Reduced snowmelt is projected to shift spring peak flow earlier in the year.[107,108] Rapid transitions in hydrology (Figure 24.5) and increasing temperatures are projected to cause widespread changes in stream conditions, shifting habitats for invertebrates and fishes.[109] While broad declines in brook and brown trout populations are projected, streams with enhanced groundwater sources have demonstrated resilience to warming and the ability to maintain a viable fishery.[110] Climate-driven changes in heavy rainfall are magnified by land use, with pronounced negative effects in urban[111] and agricultural watersheds.[26]

Extreme Precipitation Impacts



Extreme precipitation events have adverse impacts on aquatic and terrestrial ecosystems, human health, infrastructure, and economies. Conservation and management strategies can help moderate these impacts.

Figure 24.5. Extreme precipitation events can degrade aquatic ecosystems, threaten human health and safety, damage infrastructure and communities, and yield billions of dollars in economic damage. The conservation and management of natural lands can reduce these negative effects—reducing erosion and flood risk, improving water quality, increasing carbon sequestration, and reducing the economic cost of flooding. This conceptual drawing, showing a Midwestern landscape with an extreme storm on the horizon and water flowing into streams and rivers, illustrates how land management choices affect downstream flooding, infrastructure, and ecosystem services. Landscape features and land management practices that slow the flow of water across the surface can improve habitat and water quality, reduce flood and drought risks, and have a variety of other benefits. Adapted with permission from Palmer et al. 2020.[112]

As in the Northern Great Plains (KM 25.4), agricultural expansion threatens Midwestern grasslands[113] via habitat loss and land fragmentation, which exacerbates the vulnerability of grassland wildlife.[114,115] In Indiana, high temperatures and drought contributed to the local extirpation of the endangered Karner blue butterfly,[116] and portions of the Midwest may become inhospitable for the monarch butterfly due to climate change.[117] While the composition of grassland communities is changing in response to climate change, land use, and management,[118] the adoption of mowing and prescribed burning may offset global and regional drivers to retain biodiversity in these threatened ecosystems.[119,120]

Increasing temperatures are projected to increase wildfire risks to Midwestern forests.[121,122,123] Flash droughts, characterized by sudden onset and rapid intensification,[124,125] have increased in frequency since 1980—although it is unclear whether current frequencies reflect a departure from the past (i.e., before the instrumental record began[126]). Flash droughts not only impact crops (KM 24.1) but also induce significant water stress in thin-soiled forests, inciting pathogen infection that increases tree mortality.[127] Additionally, climate change combined with river management for navigation strains the health of floodplain forests that are important hotspots of ecological activity.[128,129]

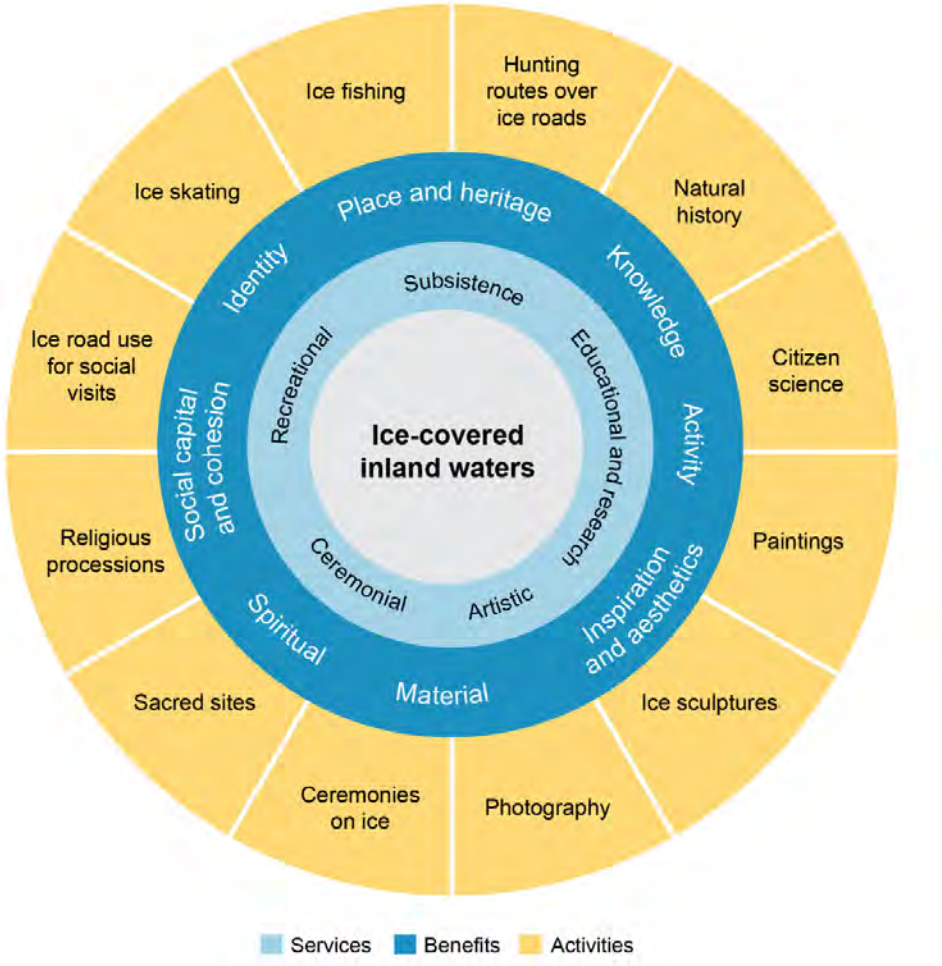
The threat of invasive species is amplified by climate change.[130,131] However, invasive species can be perceived in different ways: many Indigenous communities have holistic views of invasives, or non-local beings, who encompass both positive and negative attributes. For example, dandelions and common plantain are used medicinally in Anishinaabe communities. Understanding the gifts and teachings that beings have can change our interactions and resource management.[93,132]

Warming has shortened the length of persistent cold conditions and decreased snow cover in the Upper Midwest.[133,134] Snow supports the survival of boreal wildlife, providing insulation from cold conditions.[135] Some types of wildlife, such as moose, are threatened by warming winter conditions;[133] declining moose populations have been recorded in the 1854 Ceded Territory over the last three decades.[136,137] This loss, in turn, has cascading impacts on cultural practices, human well-being, subsistence harvesting, and tourism.[133,138,139]

Climate change accelerates the loss of beings, access, and connection to the land for Indigenous Peoples (Ch. 16).[133,140,141,142,143] Wild rice is one of the most vulnerable culturally significant species to Midwest Tribes,[5,144] and harvest rates have decreased due to warming and altered hydrology,[136,145] potentially leading to a loss of cultural identity.[5,146] Sugar maple is also culturally and economically important to Indigenous communities.[133,145,147] Warming winters have altered the timing and length of maple sugaring.[136,145] Seasonal changes and shifting habitats can impact Traditional Knowledge, language, physical health, and mental well-being by altering the timing of cultural ceremonies, availability of beings needed for the ceremonies, and potential loss of culturally significant relatives (KMs 8.2, 16.1).[145,148]

Nature-based recreation is transitioning, affecting opportunity, economy, and safety (KM 8.3). For example, climate change limits the availability of fish such as walleye and trout, sometimes leading to reduced catch limits[104] and food insecurity.[149] Ice cover, an important feature of northern lake systems, is declining in response to rising winter air temperatures,[150] with the most abrupt changes beginning in the 1990s.[4] Loss of ice cover is projected to continue through the end of the century, with greater losses under high scenarios,[150] threatening some cultural activities and services (Figure 24.6).[151] Winter drownings have also increased along with temperatures, which have decreased ice cover.[152]

Ecological Services of Ice-Covered Inland Waters



Rising winter temperatures are decreasing inland lake ice cover and the associated ecosystem services, benefits, and activities it provides.

Figure 24.6. Ice-covered inland waters provide humans with important cultural ecosystem services (light blue ring), benefits (dark blue ring), and activities (yellow ring) that are central to people's well-being, culture, and identity across the Midwest. Adapted from Knoll et al. 2019[151] [CC BY 4.0].

Nature-Based Solutions for Adaptation and Mitigation

Land managers are actively managing Midwestern forests to adapt to climate change[153] by reducing stressors, restoring native species diversity, increasing structural diversity (e.g., variation in age structure), and shifting forest composition to species better adapted to future climate conditions.[153,154] Additional studies can inform the introduction of species adapted to future climate to achieve desired forest management outcomes.[155]

Fish managers have ways to reduce the effects of increased water temperatures, novel invasive species, and other climate-driven changes.[97] They have combined socioeconomic and ecological data to prioritize lakes and identify suitable management techniques.[156] Current management interventions include acquisitions and easements, reducing runoff, protecting in-lake habitats, managing invasive species, changing harvest regulations, and adjusting stocking priorities.[156] Improvements in lake modeling and forecasting of harmful

algal blooms, as well as better information about invasive species and resilient fisheries, have the potential to improve adaptation efforts.[157]

Climate adaptation and mitigation can be achieved in part through nature-based solutions, including the protection and management of natural lands. These approaches have the additional advantage of providing social, ecosystem, and economic benefits.[158,159] Since 1980, the Midwest has incurred $49–$109 billion (CPI-adjusted to 2022 dollars) in economic damages due to flooding,[160] with losses projected to increase with further climate change.[161] Natural floodplains can reduce flood damages and yield benefit-to-cost ratios of up to 5 to 1.[162] Moreover, a targeted 10% increase of wetland area within the Mississippi River basin could decrease nitrogen loading to the Gulf of Mexico by more than 40%.[163] Additionally, climate-smart strategies on agricultural lands (Figure 24.4)[164] can yield co-benefits for Midwestern ecosystems.

There is also growing enthusiasm for natural climate solutions, which are specifically designed to increase carbon storage or decrease greenhouse gas emissions through conservation, restoration, and improved land management.[165,166,167,168] Some Midwestern forests are already being managed to bolster carbon storage,[169] and there is much room for expansion of these practices in the region (KMs 7.2, 8.3). Ongoing changes in the climate and atmosphere are expected to accelerate growth of the region's grasslands, which, depending on how they are managed, could increase their carbon storage.[170] Extensive peatlands in the region historically sequestered carbon, but much of this carbon has already been released by draining wetland areas.[171,172]

The long-term mitigation potential of Midwestern ecosystems has large sources of uncertainty related to climate-driven risk factors such as fire, drought, and pests;[165] offsets from increased soil microbial respiration;[173] and warming-induced losses of carbon stored in peatlands.[174]

Tribal Nations have made considerable progress in adaptation, including collaboration on guidance, vulnerability assessments, and implementation (KM 21.4; Ch. 16).[132,144,175] Adaptation strategies vary among Tribal Nations and their values. For example, one being might be a suitable substitute for another, such as birch trees instead of sugar maples for syrup tapping; however, beings that are tied tightly to a Tribal Nation's cultural identity (e.g., wild rice) cannot be substituted.[145] Therefore, adaptation strategies for those beings could mean collaborating and building relationships with Tribes and agencies outside of traditional harvesting lands and jurisdictional boundaries.[132,145] Inclusion of cultural knowledge and language can strengthen adaptation planning and implementation.[132,141,143,144] Guidance for incorporating this information and Tribal input by non-Tribal entities can inform respectful and reciprocal collaboration.[132,176,177]

Key Message 24.3

Climate Adaptation and Mitigation Strategies Improve Individual and Community Health

Climate change has wide-ranging effects on lives and livelihoods (*very likely*, *very high confidence*), healthcare systems (*high confidence*), and community cohesion (*high confidence*). These diverse impacts will require integrated, innovative response from collaborations between public health and other sectors, such as emergency management, agriculture, and urban planning. Because of historical and systemic biases, communities of color are especially vulnerable to these negative impacts (*very likely*, *very high confidence*). Mitigation and adaptation strategies, such as expanded use of green infrastructure, heat-health early warning systems, and improved stormwater management systems, when developed in collaboration with affected communities, have the potential to improve individual and community health (*high confidence*).

Risk

The health of Midwestern populations is at risk from increased extreme heat, precipitation, drought, and flooding, along with reductions in air quality and increased incidence of vector- and waterborne illnesses (Ch. 15). Physical injury and illness resulting from climate-related hazards may also influence mental health and can reduce quality of life and community function as traditional forms of connection and culture are lost or diminished.[178,179]

An individual's exposure and sensitivity to climate change are influenced by preexisting health conditions, age and gender, race and ethnicity, access to resources, and the level of local adaptive capacity.[179,180,181,182] Therefore, climate change impacts on health are not distributed equally across populations. Historical policies and systemic racism have created conditions that leave lower-income individuals and people of color more vulnerable to climate-related hazards (KMs 15.2, 16.1).[179,182,183,184] Environmental and social conditions such as old or deteriorating housing stock, inadequate tree cover, poor or degraded stormwater infrastructure, increased exposure to air pollution, limited transportation access, and lack of preventive healthcare services amplify climate-related hazards in the Midwest.[181,183,185]

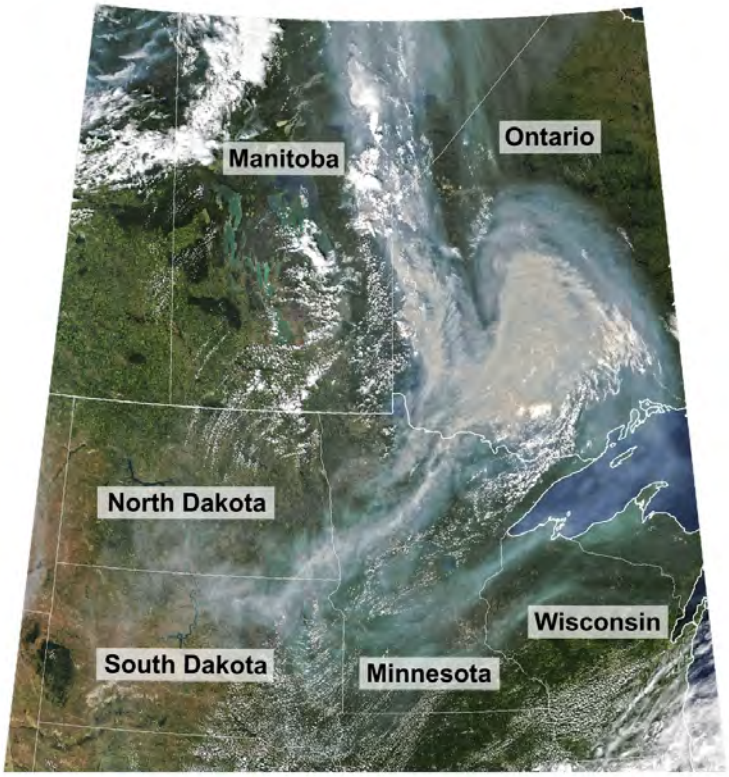
Impacts

Rising temperatures can increase the production of ground-level ozone and particulate matter (KM 14.1). Exposure to these air pollutants can cause or worsen cardiovascular and respiratory illnesses and lead to premature death.[186,187] Future warming under a very high scenario (RCP8.5) is projected to increase exposure to ground-level ozone by midcentury, with higher ozone-attributable death rates in counties in the Midwest and Great Plains than in the rest of the United States.[188] This association may be impacted by population factors, such as density and baseline death rates.[188] Mitigation efforts that reduce ozone can yield large reductions in associated healthcare costs.[189]

Projected increases in extreme heat events across the Midwest amplify the risk of heat-related and respiratory illnesses. A July 2012 extreme heat event in Wisconsin was associated with approximately $290.3 million (in 2022 dollars) in damages due to loss of life, hospitalizations, lost wages, and other health-related costs.[190] By the end of the century, approximately 1,200 deaths related to extreme heat would be avoided under an intermediate scenario (RCP4.5) compared to a very high scenario (RCP8.5).[191]

While many of the worst wildfires occur in the western US, there are scattered areas of high wildfire risk throughout the Upper Midwest (Focus on Western Wildfires).[192] Wildfire smoke from both local and distant sources (Figure 24.7) poses a threat to human health by aggravating cardiovascular and respiratory conditions such as heart arrhythmias and asthma.[89,193] A study of hospital admissions across the US between 2006 and 2015 found that an increase of 10 micrograms per cubic meter in wildfire-related particulate matter in a hospital's zip code was associated with a nearly 3% increase in probability of an intensive-care-unit admission.[194] Compared to other US census areas, this association was most consistent across Midwestern zip codes. This may be due to the larger population in this region compared to other study regions or the lack of personal protective behaviors.[194] Based on very high (RCP8.5) and intermediate (RCP4.5) future climate projections, many Midwest counties will experience increased exposure to wildfire smoke.[195]

Impacts from Wildfire Smoke in the Midwest



Wildfire smoke from both local and distant sources threatens human health.

Figure 24.7. This satellite image shows wildfire smoke from Canada moving down over the northern Midwest on July 11, 2021. Satellite image credit: Joshua Stevens, NASA Earth Observatory, using VIIRS data from NASA EOSDIS LANCE, GIBS/Worldview, and the Joint Polar Satellite System (JPSS).

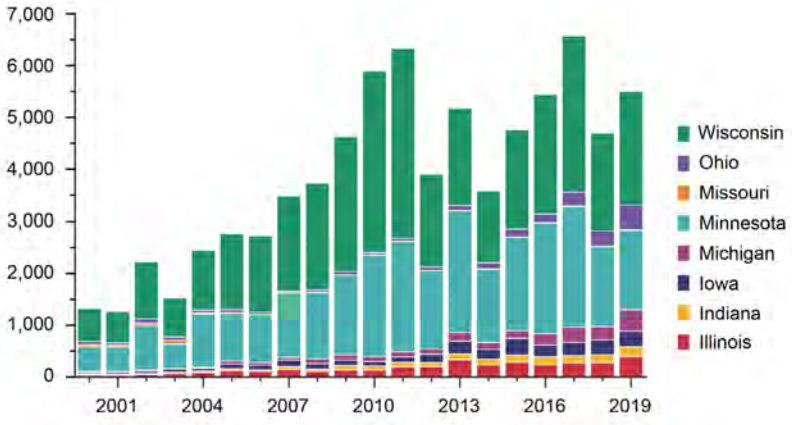
Increasing spring and fall temperatures are leading to rising pollen counts, which can worsen allergies, asthma, and other respiratory conditions (KM 14.4).[196,197] By 2050, increased oak pollen is projected to lead to a 7% annual increase in asthma-related emergency room visits for the Midwest under a very high scenario (RCP8.5) compared to 2% under an intermediate scenario (RCP4.5).[198] Notably, when sensitive individuals are simultaneously exposed to allergens and air pollutants, respiratory reactions can become more severe.[199] Black, Hispanic, and Indigenous populations tend to be disproportionately exposed to air pollution[181] and have the highest rates of asthma and asthma-related deaths and hospitalizations in the United States.[200]

The amount of precipitation falling in the most intense 1% of events increased significantly (45%) in the Midwest between 1958 and 2021 (Figure 2.8a). Under a global warming level of 3.6°F (2°C), extreme precipitation intensity is projected to increase 10%–15%, and perhaps more than 20% in some areas (Figure 2.12). Public health concerns related to flooding in the Midwest include drowning and injury, exposure to mold or waterborne pathogens, economic losses and fiscal strain, employment loss, mental stress, disruption of essential health services, and displacement from the community.[179,184,201,202]

Increases in extreme rainfall are stressing stormwater systems across urban and rural landscapes in the Midwest (KM 24.5).[164,201] Resulting sewage overflow threatens surface water and water distribution networks and increases exposure to waterborne pathogens.[201] By midcentury, precipitation changes are projected to increase the rate of gastrointestinal illness among children due to contaminated drinking water.[203] Under a very high scenario (RCP8.5), some Midwest households that rely on private wells for drinking water, most of which are outside of urban areas, are projected to be at higher risk for nitrate contamination from heavy rainfall and flooding.[204]

Rising temperatures, particularly in winter, and increasing precipitation contribute to the geographic spread of disease-carrying vectors (e.g., ticks and mosquitoes) into and across the Midwest.[205,206] Lyme disease, caused by the bacterium *Borrelia burgdorferi*, is the most prevalent vector-borne disease in the United States and is now endemic to the Midwest (Figure 24.8).[207] Health costs related to Lyme disease are substantial. One study estimated that in 2012, the health-related costs of treating Lyme disease in Michigan, which at the time was not a high-incidence state, was approximately $9 million (in 2022 dollars).[190] The tick species *Amblyomma americanum*, linked to ehrlichiosis and other serious diseases, has already been reported in the Upper Midwest, and projections indicate considerable potential expansion throughout this century.[208]

Midwest Region Lyme Disease Case Counts by State (2000–2019)



Lyme disease incidence has increased across the Midwest.

Figure 24.8. The graph shows annual reports of Lyme disease incidence across the Midwest between 2000 and 2019. Factors such as rising temperatures, increased precipitation, warmer winters and land-use change have contributed to an increase in the incidence of Lyme disease across the region. Figure credit: University of Minnesota Climate Adaptation Partnership, NOAA NCEI, and CISESS NC.

Milder winter temperatures and changes in precipitation patterns are also increasing the risk of mosquito-borne arboviruses such as dengue, chikungunya, Zika, yellow fever, and West Nile virus.[209] By 2050, areas like the Ohio Valley are projected to have approximately 99–201 annual cases of West Nile virus under an intermediate scenario (RCP4.5) or 112–231 annual cases under a very high scenario (RCP8.5).[210]

Stress associated with experiencing climate-related disasters is impacting the mental health of people living in the Midwest[179,211] and is expected to increase as the frequency of extreme events rises. The trauma caused by a disaster, such as losing one's home, job, or livelihood or being displaced from one's community, can contribute to chronic depression, anxiety, and post-traumatic stress disorder.[212,213] In addition, people can suffer a loss of social connections, bear witness to people being harmed and landscapes destroyed, and confront an uncertain future, any of which can trigger or intensify adverse mental health conditions.[178,214] Farmers and others dependent on agriculture for their livelihood are particularly at risk.[212,215,216] Many rural Midwesterners already experience obstacles to utilizing healthcare services,[217] including mental health services.[218,219]

Climate Resilience for Healthier Outcomes

Without efforts to reduce emissions and promote climate resilience, the Midwest will experience an increase in climate-related deaths, injury, and disease and a decrease in mental wellness.[220,221] Furthermore, because these health outcomes are linked to key social and environmental determinants of health, they are expected to disrupt community well-being, with costs and consequences for livelihood, social and cultural connections, education, transportation, and access to essential services.[178,182,221,222] Health disparities tied to race, ethnicity, age, and income are linked to an inequitable distribution of these climate-related health outcomes at individual and population levels.[179,184]

Actions and investments to reduce climate-related health and community impacts such as increased tree cover, weatherization programs, improved stormwater management, heat-health early warning systems, and culturally relevant climate education and climate services (Box 24.1) can yield multiple benefits for individual and community health while helping to advance more equitable climate adaptation.[182,223,224,225,226,227] Sufficient data, technical services, and tools on climate-related health risks, racial and socioeconomic disparities, and socioenvironmental determinants of health would help increase the effective management of emerging and anticipated climate and health-related risks.[182,204,227] For example, the CDC has advanced a framework for cross-sector collaboration that identifies a broad range of resources to reduce climate-related health risks.

Leadership efforts by the emergency management sector in the Midwest to address climate threats to individual and community health highlight the important role for this sector in adaptation planning.[220,228,229] The increased frequency of extreme events is expanding the need for more resources to support disaster preparedness and response, especially for vulnerable communities.[182,228,230]

Box 24.1. Midwest Educational Resources

The Midwest has a rich and expanding body of formal and informal climate education and services available to educators and resource managers of all ages and backgrounds. These efforts help build a climate-informed and responsive society and connect to impacts as well as adaptation and mitigation activities discussed throughout this chapter. Built on the National Research Council (NRC) Framework for K–12 Science Education,[231] educators from across the country created the Next Generation of Science Standards (NGSS), which includes contemporary climate science.[232] Incorporation of these standards varies across the Midwest. Illinois, Iowa, and Michigan have adopted the NGSS, while others have developed their own standards based on the NRC framework.[233] In response, educators have created new climate curriculums and activities for students across K–12 (e.g., Muhich and Rood 2022[234]). Recent federal investments, such as one establishing the Midwest Climate Adaptation Science Center,[235] augment climate research and outreach across the region, connecting with more communities and developing a stronger climate adaptation and community of practice. Since the publication of the Fourth National Climate Assessment in 2018, coordinated efforts have increased among extension professionals, who help translate climate research into practice to help rural and urban communities prepare for and respond to climate change. These and many other university, Tribal, and private entities are collaborating to expand the breadth and reach of climate education and services across the Midwest.

Key Message 24.4

Green Infrastructure and Investment Solutions Can Address Costly Climate Change Impacts

Increases in temperatures and extreme precipitation events are already challenging aging infrastructure and are expected to impair surface transportation, water navigation, and the electrical grid (*likely, medium confidence*). Shifts in the timing and intensity of rainfall are expected to disrupt transportation along major rivers and increase chronic flooding (*likely, high confidence*). Green infrastructure and public and private investments may mitigate losses, provide relief from heat, and offer other ways to adapt the built environment to a changing climate (*medium confidence*).

Risk

Midwest infrastructure, including dams, bridges, roads, wastewater facilities, and energy generation and distribution systems, need repair,[236] with estimated costs for upgrading these systems totaling $7,547 (in 2022 dollars) on average per capita across the Midwest. Projected changes in precipitation and temperatures increase the risk of failure and cost. Although the Midwest has had numerous state-level and federally declared flood disasters, the risk of loss due to recurrent, underreported inland and urban flooding events increases as the frequency of intense precipitation events rises. Fluctuating water levels make efficient navigation of goods and services through the region's rivers and the Great Lakes more challenging.

Impacts

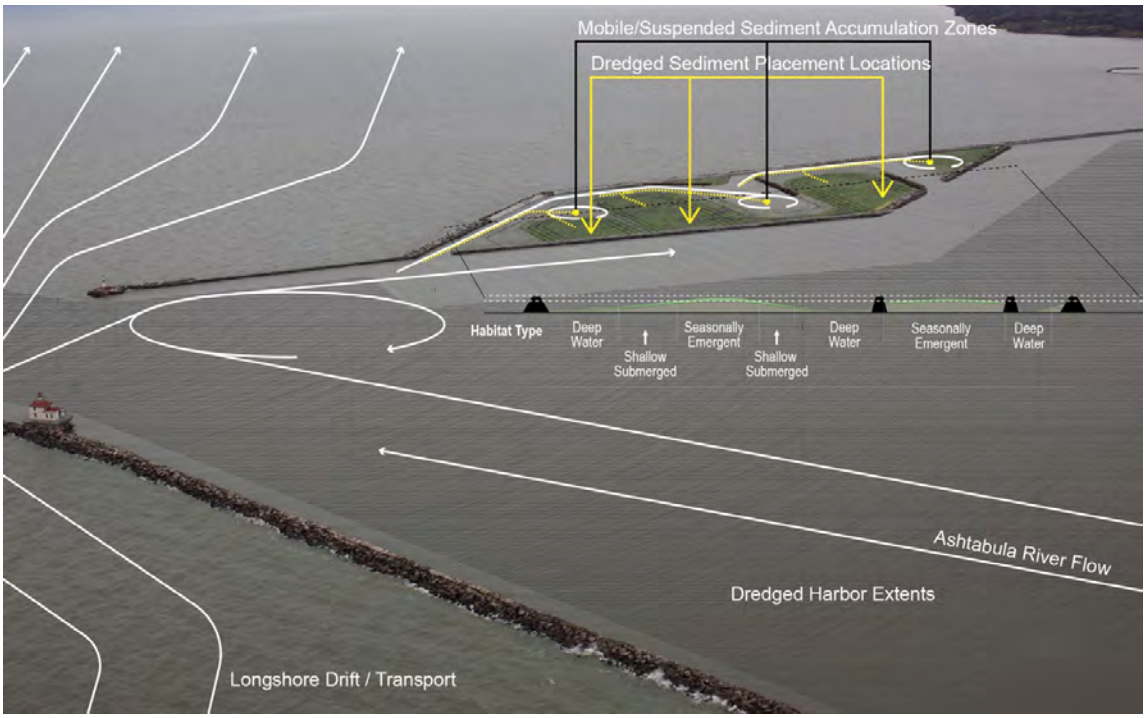
Interest in the impacts of climate change on infrastructure has grown significantly over the last decade.[237] Although improvements have been made, recent grades based on capacity, condition, funding, future need, operations and maintenance, public safety, resilience, and innovation across Midwestern states vary from a C to a D+.[236] Significant repairs are needed in surface transportation, wastewater and stormwater, dams, ports, and the energy grid. Projected increases in temperature and more intense precipitation under a very high scenario (RCP8.5) are expected to increase costs associated with rail and roads (amounting to hundreds of billions of dollars annually by 2090), with significant reductions to these estimates under an intermediate scenario (RCP4.5).[238] For instance, projected rises in temperature are expected to increase the width of cracks caused by deicing salts in reinforced-concrete bridges.[239]

The commercial transport of goods and services along the major rivers (Mississippi, Missouri, and Ohio Rivers; KM 24.5), largely controlled by a system of locks and dams, is at risk from increased precipitation extremes. High-flow events reduce traffic on the river systems, which may be limited to daytime operation only or cease altogether. During low-flow events, channels are reduced and potentially need dredging. These hydrologic extremes increase costs and lead to delays in the delivery of commodities like food and fertilizer. Along the main stem of the Ohio River, increases in the spring (March) maximum and decreases in the fall (October) minimum flow discharge are projected for 2070–2099 under high (SRES [Special Report on Emissions Scenarios] A1B) and very high (SRES A2) scenarios, with up to a 35% change expected relative to 1952–2011.[240] Without coordinated adjustments to monitoring, water releases, and communications along the river, significant disruptions to traffic flow and volume of goods transported are expected.

Water transport is the most carbon- and fuel-efficient means of transport, especially compared to rail and truck.[241] Fluctuating Great Lakes water levels, coupled with diverse ecological and geophysical conditions, create unique coastal environments that necessitate funding and construction strategies that are closely

tied to local ecological, economic, and social conditions. The period 1998–2013 saw some of the lowest water levels on the Great Lakes in recorded history, whereas the 2020s have seen some of the highest on record.[242] Great Lakes ports (Figure 24.9) are located at the vital intersections of ecological, cultural, and infrastructural systems, and port operations attempt to serve these overlapping, and at times conflicting, value systems.[243,244,245] In some cases, ports are taking on the work of ecological restoration as well as protection, property management, and urban industrial remediation—the types of efforts that can promote industrial opportunities, urban well-being, and ecological health. A good example of this is Toledo's More Than a Port initiative.[246] Another example is the multiyear Healthy Port Futures initiative, supported by the Great Lakes Protection Fund. This project reimagines how ports can function to enhance the ecological and social health of the surrounding community and ecosystem through sediment management, as well as through the ways it informs the design and restoration of public landscapes in critical nearshore habitats across the region.

Beneficial Use Wetland Creation for Healthy Ports



Innovative design of coastal infrastructure, such as the Ashtabula Port, allows the built environment to deliver social and environmental services.

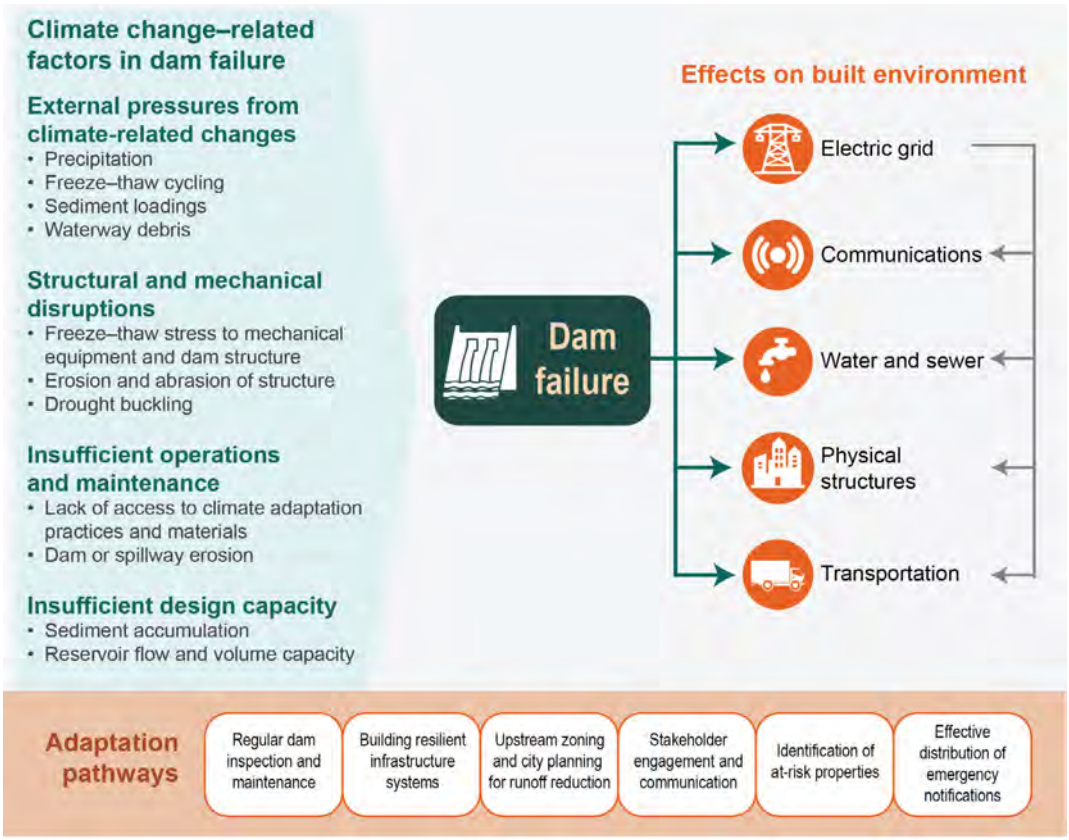
Figure 24.9. The image shows an overview of the harbor in Ashtabula, Ohio, the site of a wetland creation project by the US Army Corps of Engineers with support from Healthy Port Futures. This project, which works with the flow on the Ashtabula River into Lake Erie, was one of the first attempts in the Great Lakes to establish a partially open wetland system with reused dredge material. This design permits an occasional, ecologically necessary disturbance that will promote wetland complexity while also allowing for an important hydrological connection to the nearshore. The figure highlights areas of material placement (solid yellow lines) and sediment movement and accumulation (solid white lines, including sediment transported naturally along the shore). Sediment that accumulates in the wetland channels is placed in the dredged sediment placement locations (dashed yellow lines) every two to three years. This way, the project can employ an adaptive management approach and respond to successes and challenges that may arise. The project will create diverse habitat types including deep water, shallow submerged areas, seasonally emergent areas, and the adjacent open water areas (habits indicated by the light beige and green shading). The built project differs slightly from what is shown here. Adapted from Burkholder et al. 2022.[247]

An aging energy grid, combined with the extent and timing of a transition to different sources of energy generation, creates uncertainty about the impact of climate change on the grid itself. Increases in air temperature, rainfall, and the intensity and frequency of wildfires and storms are expected to disrupt grid efficiency and function, including maximum capacities and outage rates of transmission lines, transformers, and substations.[248] Climate change will reduce US transmission capacity by roughly 2%–8% during peak demand periods by 2100 across a range of scenarios (low [RCP2.6] to very high [RCP8.5]). Average summertime transmission line capacity reductions could range from 2%–6% under the same scenarios by the midcentury, with the Midwest seeing the largest reductions.[249] Transmission infrastructure failures, including those caused by mechanical failures and unplanned surges in electrical current, are projected to occur more frequently.[248] Given the strong push toward renewable energy and electrification of all systems, including transportation, it is uncertain whether the current grid will be able to handle the ongoing and anticipated changes in energy generation and distribution.

Renewable energy production in the Midwest has grown by more than 275% over the last decade,[250] reducing carbon emissions from the energy sector, although less so than in other regions. The growth of investment in renewable energy is contributing to the Midwest's economy. In Iowa, public interest coupled with public and private investment has advanced the state to the second-highest wind energy–producing state in the country and leading the Nation in megawatt capacity per capita. In Adair County, Iowa, investments by MidAmerican Energy Company have led to the installation of two large wind farms that are cumulatively expected to produce 550 megawatts of capacity to the grid and provide well-paying jobs.[251] However, the extent of growth in solar and wind power across the Midwest is constricted by a patchwork of state and local land-use laws and ordinances banning or regulating the siting of solar and wind power generation projects.[252]

Illinois, Iowa, Missouri, Wisconsin, and Minnesota are at high risk for increased riverine flood damage.[253] Of nearly 92,000 dams inventoried by the US Army Corps of Engineers, the average dam age is 61 years, an age when many dams require expensive repairs, and 75% are classified as high hazard potential. Climate-forced external pressures interact in complex ways, leading to effects on the built environment (Figure 24.10). Increased occurrence of extreme precipitation events stresses aging infrastructure and exacerbates the risk dams pose;[254] since 2018, 30 dam failures or near failures have occurred across the Midwest.

Climate Change–Related Factors in Dam Failure



Climate change–related factors contribute to dam failure, with cascading impacts on the built environment.

Figure 24.10. The graphic shows contributing causes for dam failure related to climate change, first-order effects of dam failure on the built environment, and adaptation pathways. Dam systems may experience climate change–related impacts independently or in parallel, and these impacts can have cascading effects. Damage to transportation, power, water, and communication infrastructure can limit a community's ability to access health services. Damage to infrastructure, land, and the built environment can negatively impact local businesses and the economy. Adaptation pathways provide a basis for communities to address dam risk from a variety of system viewpoints. Figure credit: MITRE, University of Pennsylvania, American Society of Adaptation Professionals, and The Ohio State University.

Increases in extreme rainfall events (Figure 2.8) negatively impact property, public health and safety, and transportation systems. Urban and rural communities are at risk from projected increases in frequency and intensity of extreme rainfall events. Even when events are not categorized as state or federal disasters, communities and households experience property damage from basement flooding, health impacts from sewer overflows, and traffic disruptions from storm damage.[179,255] Increases in state and federally declared disasters are expected to become more frequent. NOAA's Billion-Dollar Weather and Climate Disasters tracking data now offer a detailed analysis of disasters reaching this cost impact, but smaller events are difficult to assess.[160]

Moving away from disaster-struck areas is more difficult for people with low income than it is for wealthier populations.[256,257,258] Billion-dollar disasters and smaller-scale disasters alike have led to individual property damage and, in some cases, complete loss. A history of repairing buildings after repeated disasters has led to cases where structures have been rebuilt more than 30 times at a cost of nearly 100 times the value of the property.[259] Between January 1989 and August 2019, more than 18,000 structures experienced chronic

losses in Ohio, Iowa, Illinois, and Missouri.[260] Repetitive losses are trending upward due to increases in extreme storms and flooding across the region. Some Midwest communities are facing relocation due to projected increases in heavy precipitation and increased flood risk. Managed retreat, or community relocation—moving an entire community out of harm's way—is often discussed as a coastal adaptation measure, but it has applied to the Midwest for decades. Examples, including the town of Valmeyer, Illinois, and the relocation of the Bad River Band of Lake Superior Chippewa in Odanah, Wisconsin, offer lessons on the benefits and drawbacks of flood-induced relocation. Equitable and effective relocation benefits from the coordination of dozens of jurisdictions and substantial funding and often takes years to achieve.[259] These relocation efforts can disrupt social relationships and institutions.[261] As described in Box 20.1, successful and equitable relocation programs require strong community engagement and an open recognition of the multiple drivers of migration, including environmental, economic, and governance conditions.

Innovative Finance and Investments

Recent federal funding from the Infrastructure Investment and Jobs Act is pushing funding to state and local governments to support long-delayed infrastructure upgrades and repairs. As of March 2023, more than $36 billion (in 2022 dollars) in project funding has been invested or announced for infrastructure projects in the Midwest, with an average 15.5% of funding directed toward climate, energy, and environment projects.[262] Along with this infusion of public dollars, the infrastructure investment landscape is changing, with private investment, environmental impact bonds (EIBs), and other financing tools being used in the region. An EIB is a financing tool that allows private investors to provide up-front capital for a pilot project or to scale up an existing project, with the goal of achieving a set of environmental outcomes. Some localities have combined innovative infrastructure approaches, including green infrastructure, with new funding models like EIBs or public–private partnerships. An innovative finance and construction approach being used by the Milwaukee Metropolitan Sewer District (MMSD) is an example of proactive climate adaptation. The MMSD reduced the annual number of combined sewer overflow events from 50–60 in the early 1990s to 2.3 in 2019. Using a community-based public–private partnership, the MMSD is now looking to add an additional 20 million gallons of green stormwater infrastructure (GSI) capture capacity beyond the current capacity of 40 million gallons. The project will allow for public and private investment to support local business and achieve massive green infrastructure benefits by 2026.[263] Other municipalities are implementing GSI, and it is estimated that private investments across Ohio, Wisconsin, Minnesota, Illinois, and Indiana can support more than a billion dollars of GSI.[264] Aside from leveraging private investment, some municipalities are combining funding from multiple public sources, including from different agencies and at different scales of government (federal and state) to fully fund projects. In the case of the Bee Branch Watershed Flood Mitigation Project in Dubuque, Iowa, eight federal and three state funding sources have been applied to the $250 million (dollar year not reported) project.[265]

Careful placement and design of green infrastructure provides benefits beyond flood reduction, such as reducing the urban heat island effect and providing relief to city residents during heatwaves. Green infrastructure such as increased vegetation, stormwater capture systems such as bioswales (vegetative areas that concentrate and move stormwater while filtering for debris and pollution) and detention ponds, and open green spaces can significantly lower temperatures and channel natural airflow, which enhances the cooling effect from the green infrastructure.[266]

Key Message 24.5

Managing Extremes Is Necessary to Minimize Impacts on Water Quality and Quantity

Climate-related changes to water quantity and quality are increasing the risks to ecosystem health, adequate food production, surface water and groundwater uses, and recreation (*high confidence*). Projected increases in droughts, floods, and runoff events across the Mississippi River basin and the Great Lakes will adversely impact ecosystems through increased erosion, harmful algal blooms, and expansion of invasive species (*likely*, *high confidence*). Federal and state agencies and nongovernmental organizations are cooperating on adaptation efforts related to streamflow, water quality, and other water issues (*high confidence*).

Risk

Climate change is affecting the quality and quantity of water in the Midwest, as well as management practices related to the health of human and natural systems.[267] Across both the Mississippi River and Great Lakes basins, climate change has impacted streams, rivers, and lakes—all vital to urban, rural, and Tribal communities. Drinking water sources, private wells, and agricultural irrigation sources are at risk. Observed changes in hydrology include increases in the variability of lake levels, evaporation, and water temperatures, along with more intense precipitation,[268] including lake-effect snow, and shorter duration of snow and ice cover. These changes impact food production, businesses, industries, tourism, and recreation. Ecologically sensitive aquatic systems in the Great Lakes are at risk due to changes in lake temperatures and invasive species (KM 24.2).[269]

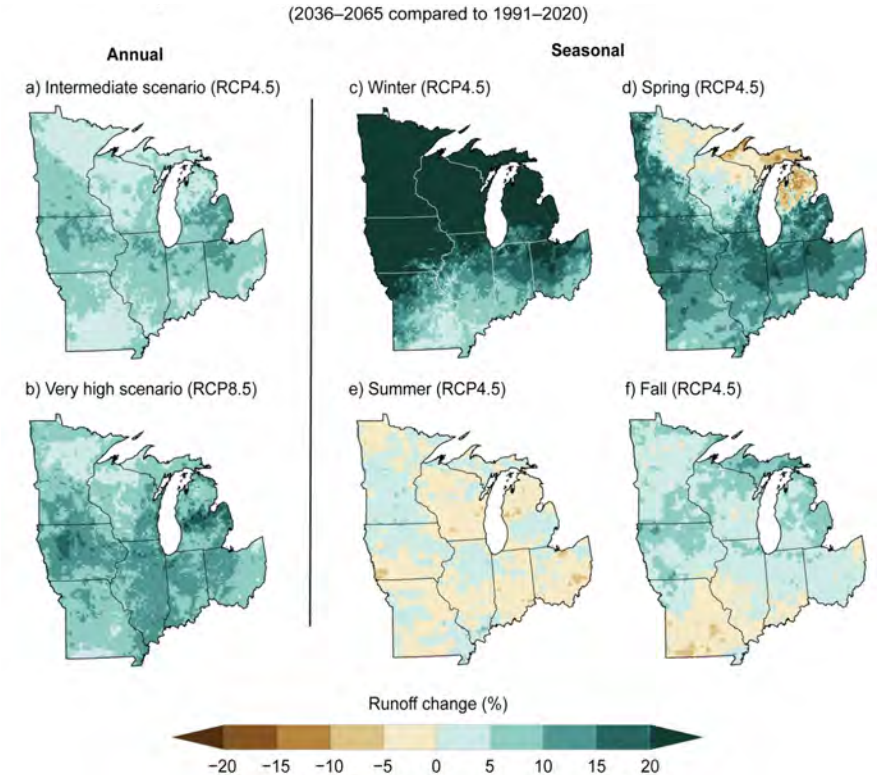
Impacts

Mississippi River System

The Ohio River, upper Mississippi River, and lower Missouri River are susceptible to floods and droughts based on projected changes in precipitation, evapotranspiration, and soil moisture (Ch. 4). Precipitation has increased in recent decades (Ch. 2) with more extreme variability and rapid shifts between wet and dry periods (Figure 24.1). Projections across a range of scenarios (low [SSP1-2.6], intermediate [SSP2-4.5], and very high [SSP5-8.5]) indicate future increases in annual precipitation of 0.3% to 1.5% per decade in the eastern Midwest and 0.2% to 0.5% in the western Midwest.[15] Winter and spring precipitation is expected to increase, while summer and autumn precipitation is projected to be more variable.[15]

Cumulative runoff has increased in recent decades[240] and is projected to continue increasing through midcentury (Figure 24.11), leading to increased riverine flooding in the Ohio, upper Mississippi, and parts of the Missouri River basins. Prolonged periods of increased cumulative runoff have adversely impacted ecosystems and commerce and are projected to continue to do so.[240] Observed decreases in the length of winter have reduced snowfall across the Midwest,[270] with negative impacts for snow-dependent winter tourism for the Midwest and Great Lakes (KM 24.2).[178] By the end of the century, projections indicate reductions in snowstorm frequency and size and snow-water equivalent totals;[271] shorter snow seasons; and fewer intense snowfall events.[272]

Projected Changes in Cumulative Seasonal and Annual Runoff



Projected changes in cumulative local runoff will lead to increased flooding susceptibility in winter and spring, with increased flash drought potential in summer.

Figure 24.11. The maps show projected changes in the annual approximate cumulative gridded local runoff generation (referred to as cumulative runoff) for intermediate (RCP4.5) and very high (RCP8.5) scenarios (**a**, **b**) and seasonal approximate cumulative runoff for an intermediate (RCP4.5) scenario (**c**–**f**). The cumulative runoff is defined as the gridded cell-by-cell ability of the landscape to generate excess water for potential downstream river runoff using the Variable Infiltration Capacity (VIC) land-surface model. The cumulative runoff was developed using Coupled Model Intercomparison Project Phase 5–modeled scenarios and the VIC hydrology model. Cumulative runoff is projected to increase annually across the Midwest between 2036 and 2065 compared to 1991–2020 (shown in percent changes). Cumulative runoff increases are expected throughout the region in winter and across all but the northern Great Lakes in spring and southern Midwest in fall. Summer cumulative runoff is projected to be more variable. The result of the projected increases (and in summer, both increases and decreases) in cumulative runoff will be increased stresses to ecosystems, the built environment, natural and water resources, and agriculture. Figure credit: NOAA NWS, NOAA NCEI, and CISESS NC.

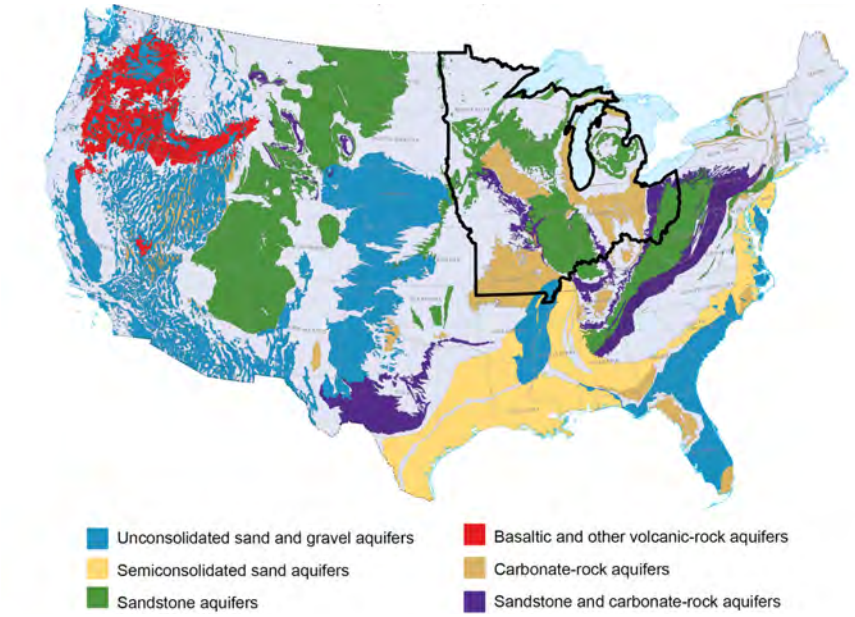
Midwest droughts develop in response to precipitation deficits or extremely high temperatures and evapotranspiration (KM 4.1). In recent decades, evapotranspiration has become, and is expected to continue to be, the dominant driver of drought,[273,274] especially across the eastern Midwest.[275] Precipitation deficiencies remain the primary driver of increased drought in the southwestern Midwest.[276]

Groundwater storage is important for water resource management, including wastewater permitting, water supply, and fisheries. Groundwater recharge is projected to be variable in the Midwest,[277] with water imbalances[28] resulting from precipitation and evapotranspiration changes. Failure of private wells is expected to increase during droughts as water tables drop with increased irrigation and water usage.

Vulnerability to water shortages and water quality depend, in part, on the primary source for water use and drinking water for any given location (aquifers/deep groundwater versus surface/shallow groundwater;

Figure 24.12). Thus, drought occurrences will have different impacts based on the source. For surface water, decreases in summer runoff (Figure 24.11) can reduce water quality and streamflows.[278] Aquifers, on the other hand, are more resilient to rapid hydrological transitions but are still impacted by longer-term drought conditions.[278] Precipitation is projected to increase in all seasons, while runoff is projected to increase in the cool season but become more variable in the warm season (Figure 24.11). The combination of warming temperatures and more variable summer runoff suggests an increased risk of drought for people, crops, livestock, and ecosystems across the region.[240] At the same time, increased precipitation and runoff events (Figure 24.11; KM 4.1) are expected to increase nuisance flooding (KM. 24.4) and sewage spills and resulting odor releases, as well as deteriorate water quality due to increased uncontrolled discharges. Stormwater runoff increases are expected to harm aging infrastructure and lead to higher costs for new systems (KM 24.4). Thus, urban and rural managers are implementing best practices for water quality across diverse landscapes, from agriculture (Figure 24.4) to forests (Figure 24.5) and the built environment (KM 24.4).[164]

Map of US Aquifers



Vulnerability to disruptions in water quality and quantity varies by location, depending on the primary source of water for drinking and other uses.

Figure 24.12. The USGS Ground Water Atlas of the United States provides a complete summary of the Nation's groundwater resources and includes the location, geography, geology, and hydrologic characteristics of the major US aquifers. Surface water and groundwater (aquifers) are the primary sources of water in the Midwest and Great Lakes. The areas highlighted in color represent groundwater aquifers, while areas in gray represent surface water as the main source. The black boundary outlines the Midwest region. Changes in rainfall and runoff patterns impact water availability and water tables differently across the Midwest, depending on whether the main source of water is surface- or aquifer-based. For more information on aquifers outside the contiguous US, visit the USGS Ground Water Atlas of the United States and Principal Aquifers of the United States. Adapted from USGS 2021.[279]

Harmful algal blooms (HABs) and their impacts to water quality, food production, recreation, tourism, and ecosystems continue to be a major concern across parts of the Midwest. Observed increases in precipitation[15,268] are resulting in, and are projected to continue to result in, increases of sediment and nutrient loads in the Mississippi River system. However, research has been inconsistent about whether HAB severity and magnitude in the Midwest have been increasing, remaining constant, or decreasing.[280,281]

Great Lakes

The Great Lakes are the largest freshwater ecosystem on Earth[282] and are among the fastest-warming lakes in the world.[283] The Great Lakes Water Quality Agreement between the United States and Canada established a suite of nine indicators to assess the ecosystem health of the Great Lakes (Table 24.1). While efforts to restore and protect the Great Lakes are ongoing, this ecosystem is at risk from shifts in seasonality (changes in the timing of the formation and destruction of temperature stratification) and from changes in ice cover, maximum summer temperatures, and oxygen levels, which have significant impacts on fisheries and habitats in the lakes.[282] Invasive species and threats to biodiversity are the greatest concerns of the Great Lakes.[282] Aquatic invasive species (KM 24.2) can degrade water quality by decreasing water clarity, concentrating toxins, and altering nutrient flows within the food web. Great Lakes water quality across a wide range of metrics currently ranges from fair to good.[282]

Table 24.1. State of the Great Lakes 2022 Assessment

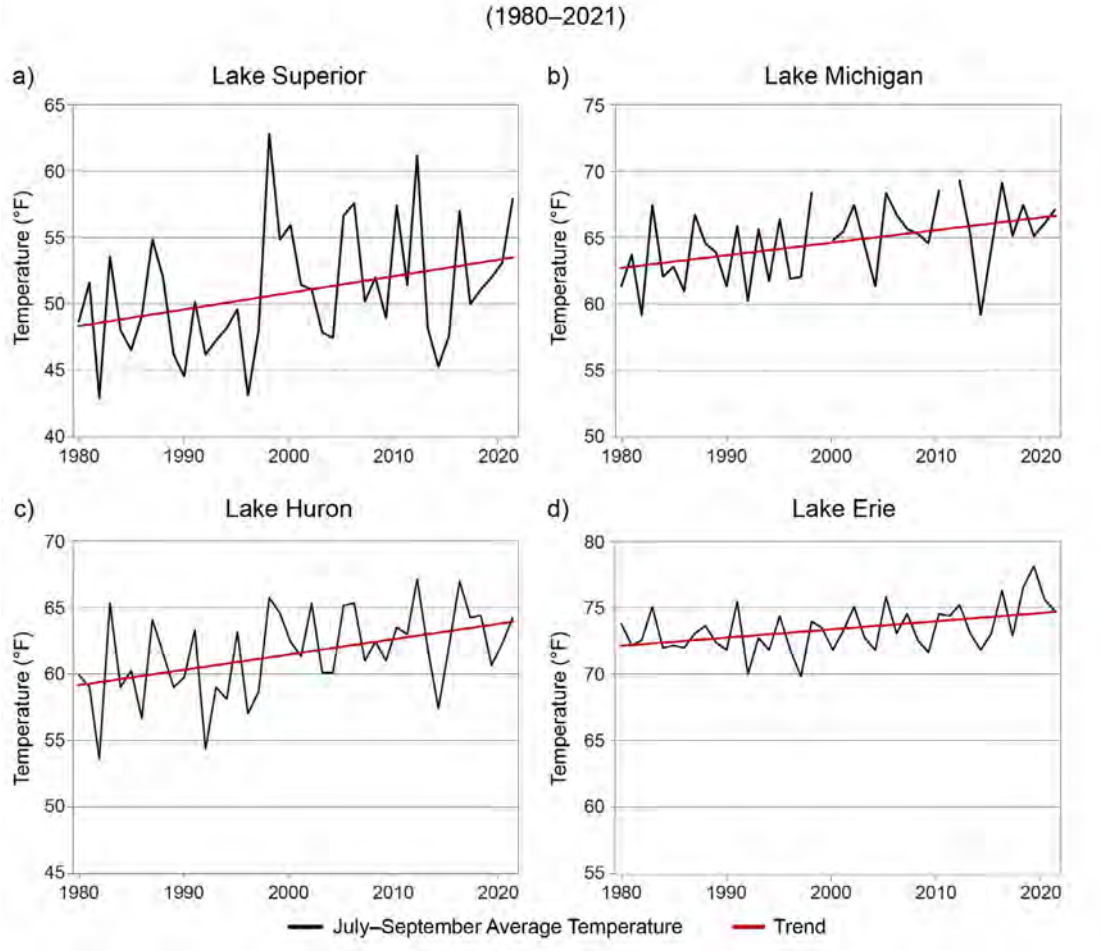
CAPTION: The EPA and Environment and Climate Change Canada work jointly to meet the mission of the Great Lakes Water Quality Agreement. As part of this effort, the State of the Great Lakes Report is released every three years. The following table details the state of the Great Lakes using 10 Indicators. The assessments are basin-wide and typically vary between lakes. The metrics listed are synthesized to determine the status and trends of each indicator. The definitions for "poor," "fair," and "good" are quantitative, vary between indicators, and are documented in the report (ECCC and EPA, 2022).[282] Status assessments are not provided for the climate trends indicators. Adapted from ECCC and EPA 2022.[282]

Great Lakes Indicator	Metric	Status	Trend
Drinking Water	US/Canadian drinking water standards (microbial, radiological, chemical)	Good	Unchanging
Beaches	*E. coli* assays	Good	Unchanging–improving
Fish Consumption	Polychlorinated biphenyls [PCBs] and mercury in fish flesh	Fair	Improving
Toxic Chemicals	Concentrations of compounds (PCBs, mercury, polybrominated diphenyl ethers, and others) in sediment, water, whole fish, and herring gull eggs	Fair	Unchanging–improving
Habitat and Species	Overall health and habitat conditions and availability of invertebrates, fish, amphibians, birds, plants, connectivity	Fair	Unchanging
Nutrients and Algae	Nutrient concentration, harmful algal blooms, *Cladophora*	Fair	Unchanging
Invasive Species	Rate of introduction	Good	Unchanging
Invasive Species	Aquatic invasive species impacts	Poor	Deteriorating–unchanging
Groundwater	Chloride/nitrate concentrations	Good	Undetermined
Watershed Impacts	Forest and land cover, hardened shorelines, tributary water quality, human population	Fair	Unchanging
Climate Trends	Lake levels	N/A	Unchanging–increasing
Climate Trends	Surface water temperature	N/A	Increasing
Climate Trends	Ice cover	N/A	Decreasing

The Great Lakes have witnessed significant water-level variability over the last several decades, with low water levels from 1998 to 2013 and high-water levels since 2015. This variability is due in part to changes in the seasonality and intensity of precipitation (including lake-effect snow), warmer lake temperatures, lake evaporation, and loss of ice cover.[284] The twin stressors of increases in precipitation and air temperature result in increased interannual variability in lake levels.[285] However, the complex interactions between lakes, land, and atmosphere make the system difficult to model, so that long-term projections of net basin supply and lake levels have high uncertainty.[6] These climate changes impede current water management practices for the Great Lakes, which are similar to those elsewhere in the Midwest, with the added challenge of transboundary water agreements with Canada (Ch. 4). For example, low water levels limit power production from hydropower facilities and pose risks to shipping[286] and ports (KM 24.4), while high water levels lead to shoreline erosion, loss of coastal habitat[287] and flooded communities. Shorelines are also at risk from high-wind events during high-water-level episodes.[288]

Great Lakes water and air temperatures have been rising since 1980[282] (Figure 24.13). Summer surface water temperatures recorded by offshore buoys have shown nearly uniform increases across the upper Great Lakes (Superior, Michigan, and Huron). Lake Erie shows slower warming rates, while there are not enough data from Ontario to make a determination. Increases in lake surface temperatures are expected on all five lakes.[289] Although uncertainty remains on the seasonal and spatial variability, increased temperatures are expected to result in loss of suitable fish habitat.[290] How the surface warming will affect the rest of the water column and the overall impact on the ecosystem is not as well characterized. Coupled with increasing water temperatures is a decrease in winter ice cover,[291] which is observed on all five lakes and has cascading impacts on ecosystems and culture (KM 24.2; Figure 24.6).

Great Lakes Summer Surface Water Temperature Trends



Summer surface water temperatures have been increasing for Lakes Superior, Michigan, Huron, and Erie since the late 1970s.

Figure 24.13. The graphs show summer (July–September) surface water temperatures for the period 1980–2021 observed from buoys in the offshore waters of Lakes Superior, Michigan, Huron, and Erie. The upper lakes (Superior, Michigan, and Huron; **a**–**c**) show similar trends toward warmer temperatures against a background of strong interannual variability, while Lake Erie (**d**) shows a weaker but still positive trend. To facilitate comparison of trends, a temperature range of 25°F is used for the vertical axis on all four charts, with actual temperatures varying across the different lakes. Figure credit: University of Minnesota Duluth, NOAA NCEI, and CISESS NC

HABs occurring in portions of all five of the Great Lakes, including western Lake Erie and parts of Lake Superior, are affecting people through poor water quality and advisories against swimming and beachgoing. HABs also negatively impact habitats and fisheries. Projected increases in cumulative annual runoff (Figure 24.11), which elevate the risk of nonpoint-source pollution (natural and human-made pollutants that are carried from many sources by precipitation and runoff) and warming trends across the Great Lakes (Figure 24.13), are expected to promote the growth of HABs through midcentury. Although the direction of change of HABs across the Midwest is inconsistent,[280,281] recent trends in western Lake Erie show a significant increase in the extent and severity of HAB events over the last 20 years.[282]

Managing Hydrologic Complexity and Extremes

Federal, state, and local governments and institutions are working with communities on initiatives to adapt to and/or lessen the impacts of climate change. For example, the US Army Corps of Engineers has partnered with federal agencies, nongovernmental organizations, and institutions on the Ohio River Basin Climate Change project.[240] The goal was to create a comprehensive plan to address changing streamflows and identify adaptations needed to deal with water quantity, quality, and management challenges related to regulations, recreation, navigation, and aquatic habitats (e.g., fisheries). A similar study with NOAA and the University of Minnesota for the upper Mississippi River basin kicked off in 2022. Additionally, a number of climate resilience partnerships throughout the Midwest and Great Lakes have been completed.[292]

As part of the National Integrated Drought Information System, the Midwest Drought Early Warning System was established in 2016 to advance drought monitoring, forecasting, and preparedness in the region and to improve regional capacity to respond to drought.[293,294]

To adapt to extreme runoff, strong private and public partnerships can help formulate best management practices for reducing nutrient and sediment loads into streams and rivers. NOAA is accomplishing this through the Runoff Risk Decision Support project.[295] NOAA is working with state departments of agriculture in parts of the Midwest and Great Lakes, including Minnesota, Wisconsin, Michigan, and Ohio, as well as New York. The NOAA Runoff Risk Decision Support tool provides the agriculture community with timely forecast information on when to apply fertilizers. Most fertilizer applications are executed in the Midwest and Great Lakes during the winter into spring just before planting season, which is also peak runoff season. A significant percentage of total nutrient and sediment losses typically occur from a small number of runoff events each year.[296,297] The information provided by this tool allows farmers to make better-informed decisions on when to apply manure and fertilizer. The correct application of manure and fertilizer will reduce the risk of chemicals entering into river systems. The reduction of excess chemicals, including nitrogen and phosphorus, entering into waterways is important, since high nutrient and sediment loads contribute to impactful environmental HAB and hypoxia (low oxygen level) events.[297] The Mississippi River/Gulf of Mexico Hypoxia Task Force and the US/Canada Great Lakes Water Quality Agreement highlight the need for nutrient load reductions in the Mississippi and Great Lakes watershed systems, due to increasing impacts on both the public health system and ecosystems.[298]

Traceable Accounts

Process Description

The Midwest chapter authors were identified and recruited in August and September of 2021. The goal was to construct the team with at least one author from each of the Midwest states, with attention to geography, interconnected systems, level of expertise, gender, and diversity. The selection of authors was based on Federal Registry Notice comments, USGCRP (US Global Change Research Program) Research Gaps Summary for the Midwest, and author nominations, as well as discussions and nominations by the chapter lead, coordinating lead author, agency chapter lead, and National Coordination Office point of contact. Authors were added iteratively, with those who accepted early providing additional suggestions for subsequent nominations. All but two of the invited authors agreed to participate.

Regular virtual meetings were held during the fall of 2021, with the Zero Order Draft finalized in December 2021. The Midwest chapter hosted a virtual public engagement workshop on January 24, 2022. The key topics selected were well received, with ample discussion and feedback. Authors considered the comments along with inputs provided in the public call for technical material and incorporated the available recent scientific literature in developing the Key Messages for the First Order Draft. Author consensus was built through routine meetings and based on feedback from the NOAA Technical Support Unit (TSU); federal agencies; the National Academies of Sciences, Engineering, and Medicine; and public comment review periods. This iterative process occurred between the Second and Fourth Order Drafts, from the winter of 2022 to the spring of 2023.

Key Message 24.1

Climate-Smart Practices May Offset Complex Climate Interactions in Agriculture

Description of Evidence Base

There is strong evidence that increasing extreme precipitation events, changing seasonality, and rapid transitions between hydrologic conditions are negatively impacting soil conditions and challenging traditional row crop agricultural production in the Midwest, with uncertainty remaining due to local climate influences and limitations with downscaled climate data.[12,18] Studies link the loss of soil and applied nutrients to increasing rainfall, with cascading impacts including financial loss and increased water quality issues. Numerous studies point to future decreases in corn production, in combination with episodic drought, and increases in the production of some crops like wheat due to cooler-season changes including warmer springs and greater rainfall (e.g., Li et al. 2019[2]). Impacts on animal agriculture in the region remain an understudied topic, although some studies have shown impacts are already occurring (e.g., Crist et al. 2020[51]). Many of these projected impact studies rely heavily on a very high scenario (e.g., RCP8.5), which limits the assessment of the full range of uncertainty.

Reports and studies strongly demonstrate the economic importance of specialty crops to the Midwest and their vulnerability to climate change.[56] Most studies to date focus on the impact of spring-freeze injury, although a limited number of studies address other impacts such as excessive moisture, disease, and pest pressure. Evidence suggests a wide range of future outcomes to specialty crops based on species and location of cropping systems within the Midwest. Studies on the direct impacts of rising temperature and altered precipitation patterns on specialty crops across the Midwest remain limited. The evidence base for the impacts of climate change on important pollinators and insect species distributions is growing.

An increasing number of studies address agriculture's impact on climate, particularly the intensification of cropping systems and potential impacts from increased irrigation.[46] Impacts on atmospheric moisture and feedback loops within the system are ongoing.

Studies have linked, at least in part, climate change to crop insurance losses across the US and the Midwest.[75] These losses are related to drought and excess moisture. Building resilience to these hazards is part of a climate-smart approach. Studies to evaluate specific benefits and other impacts from varying climate-smart techniques are evolving.

Major Uncertainties and Research Gaps

Current climate trends are, in some ways, counter to projected climate conditions and differ from other regions of the country. For example, summer daytime warming trends (daily maxima) and drought are not occurring as projected by previous model simulations. Historical changes have been much more seasonally dependent, with the largest increases in temperature occurring during the cooler seasons rather than the summer. A high degree of uncertainty also exists in individual model-projected changes in the intensity and seasonality of future precipitation, as well as the attribution of these complexities to anthropogenic sources. While model consensus strongly points to overall increases in annual temperature, additional investigations on the interactions between agriculture and its impact on climate in the region would help resolve seasonal discrepancies. Reductions in model and scenario uncertainty would improve local impact assessments and decision-making.

More detailed information about projected changes in other climate parameters (e.g., vapor pressure deficit, soil moisture, extremes, and severe events) and impacts on specific crops would be needed for a broader understanding of the potential impacts on agricultural production and increased confidence in the findings. This includes studies beyond corn, soybean, and wheat, including other cash and specialty crops (e.g., apples, pumpkins, cucumbers). Detailed information on secondary climate change impacts (i.e., increased insect, disease, and weed pressure on production) is less well understood as well. Analyses of historical changes in the distributions of agricultural pests are limited, as are model projections of their future distributions.

With respect to social equity and justice concerns for agriculture in the Midwest, identifying and increasing engagement with BIPOC (Black, Indigenous, and People of Color) communities and low-resourced communities across the Midwest could increase the sharing of information and bring resources to these communities to enhance their climate adaptation and mitigation activities already underway. This would lead to a more informed and full assessment of the impacts, adaptation, and mitigation agricultural activities already taking place within these communities. There have been recent federal investments, for example, that have infused support into National Institute of Food and Agriculture programs that bring social and physical scientists together to help fill in this knowledge gap. Work from these new projects could be sought for future National Climate Assessment reports.

Research activities on the ability for climate-smart practices to help agriculture adapt to changing climate conditions and lessen future issues are increasing. However, further investigation of the potential trade-offs between strategies and a diverse set of outcomes based on crop, cover, soil type, and local changes in climate would be needed to increase confidence in their use and whether they reach desired outcomes. Research does support some climate-smart practices, but widespread implementation and interaction of various practices is poorly understood.

Description of Confidence and Likelihood

Based on numerous studies and converging evidence, there is *high confidence* and it is *likely* that climate change is negatively impacting agriculture in various ways. Examinations of historical extreme precipitation events and rapid transitions between hydrological states through novel analysis techniques show that these phenomena are *likely* increasing in number, and projections show that they are *likely* to continue throughout the 21st century. The team focused on the challenges, including poor field conditions and potential crop losses, that are *likely* to accompany these changes in the hydrological conditions. Although crop impacts are *likely* based on similar results across scales and methods, uncertainty in specific impacts by species (crop, insect, etc.) leads to *medium confidence* in future outcomes of row and, especially, specialty crops. Other *likely* changes, including snowmelt timing and extreme precipitation events in spring, will lead to additional impacts on animal agriculture in the region, and attention was given to dairy production as a major component of animal agriculture in the Midwest (*high confidence*). Climate-smart adaptation techniques provide a potential path toward environmental and economic sustainability, but the limited converging evidence and adoption to date lead to overall *medium confidence* in their ability to mitigate future agricultural challenges.

Key Message 24.2

Adaptation May Ease Disruptions to Ecosystems and Their Services

Description of Evidence Base

Strong convergent evidence from many sources in the published and gray literature shows that climate change is impacting natural resources in the Midwest and that these impacts will further intensify with advancing climatic change. However, the amount of evidence varies by ecosystem, the particular type of environmental change, and geographic location within the Midwest.

Strong convergent evidence from published studies shows that Midwestern aquatic ecosystems are responding to increasing temperatures and to changes in extreme weather.[97,99] There is a moderate amount of evidence demonstrating that these systems are responding to increasing precipitation. Several studies show that flooding and drought pose increasing risk to aquatic ecosystems, specifically by altering structure and community dynamics.

The evidence from published studies demonstrating that terrestrial ecosystems are being altered by climate change is strong overall (e.g., Contosta et al. 2019[133]), although the amount of evidence for any given ecosystem type being affected by any given environmental change is variable. Evidence supports the finding that impacts have been more pronounced in more northerly parts of the Midwest. Overall, there is unequivocal evidence that Midwestern ecosystems have been and will continue to be affected by landscape change, and many studies link changes in the functioning of these systems to rising temperatures and reduced snow and ice cover.[133,151] There is strong evidence that these climatic factors have been changing in the Midwest.

Major Uncertainties and Research Gaps

Much of the uncertainty concerning Midwestern natural resource responses to climate change is linked to the varying responses across species, ecosystems, and geographic location. Many species and some ecosystems are subjects of few or no direct studies; some variables have been studied in only one location within the Midwest; and species interact in complex ways that could potentially lessen or reverse direct effects of climate change in some cases—all of which increase the uncertainties of projected climate change responses.

Assessing projected responses to climate change can be challenging because of scale mismatches with climate model output. For example, streams are much smaller than climate model grids and as such require offline downscaling. Although this has been done, it has not covered the breadth of Shared Socioeconomic Pathway (SSP) scenarios.

There is significant uncertainty concerning how widely human communities are adapting their cultural practices to climate change and whether adaptation strategies have documented benefits. Case studies are available,[145] but more information is needed across the full spectrum of Midwestern communities.

Description of Confidence and Likelihood

Broad evidence from published studies indicates it is *likely* that climate change is impacting natural resources in the Midwest (*high confidence*). Published studies show that flooding and drought *likely* pose increasing risk to aquatic ecosystems by altering structure and community dynamics, although agreement on the precise magnitudes of effects is less clear (*medium confidence*). Numerous studies show that rising temperatures, altered winter conditions, and landscape changes are *very likely* altering terrestrial ecosystems and limiting their adaptive capacity (*high confidence*). This is particularly pronounced in northern ecosystems. Emerging evidence shows that losses of ecosystem services are undermining human well-being, causing the loss of economic, cultural, and health benefits (*medium confidence*). Owing to the site- and ecosystem-specific nature of the evidence, it is difficult to make broad generalizations across the Midwest. People are adapting management and cultural practices in response to climate change, particularly for inland lakes and forest systems; many of these practices have co-benefits for ecosystem services, including mitigation of climatic changes (*low confidence*). The authors assess with *low confidence* because of noted knowledge gaps across the Midwest concerning both community actions and documented responses.

Key Message 24.3

Climate Adaptation and Mitigation Strategies Improve Individual and Community Health

Description of Evidence Base

There is strong evidence that increasing temperatures and changes in historical precipitation patterns are occurring across the Midwest and will *likely* continue through the end of the century. The level of air contaminants, such as particulate matter, ozone, and pollen, are positively associated with rising temperatures, and there are numerous studies describing the link between exposure to these contaminants and increased morbidity and mortality.[186,187]

Exposure to climate-related events, such as extreme heat and flooding, has been shown to impact the health and well-being of Midwest communities, as well as degrade social and environmental determinants of health.[178,179] The occurrence of extreme heat and precipitation events is projected to rise across the Midwest. However, there are few in-depth qualitative assessments that capture and report person- or community-specific information from those impacted, particularly the short- and long-term effects of experiencing a climate-related hazard. Increases in intense rainfall have been linked to increased exposure to waterborne contaminants in both public and private drinking water systems in the Midwest.[201,204] Studies using climate projection data have shown that climate-related seasonal precipitation changes will increase the rates of gastrointestinal illness in children.[203]

There is strong evidence that rising temperatures are contributing to the expansion of disease-carrying vectors like ticks and mosquitoes into and across the Midwest.[207] Modeling using climate projections

predicts that the range of many established and newly invasive species will increase throughout the century, increasing the risk of various zoonotic diseases like Lyme disease and West Nile virus.[208]

Climate change is associated with negative impacts on mental health.[211] However, there are few studies, particularly based on Midwest populations, that link robust measures of climate change or climate-related events with clinically validated psychiatric diagnoses.

There is a substantial increase in the number of climate assessments conducted for Midwest states and cities that emphasize the need to address systemic injustice and historical racism and prioritize equity in climate resilience decision-making.[32,299,300] Many of these reports also acknowledge the need to involve disproportionately impacted communities in the design and implementation of resilience strategies. These assessments are not part of the peer-reviewed literature and thus were not considered as part of the evidence base for this section. However, it is notable that many Midwest climate assessments have not only included but also prioritized these issues as part of their climate resilience planning.

Major Uncertainties and Research Gaps

While there are many studies linking climate change to impacts on health and community well-being, only a small number of these studies have been conducted directly or solely on Midwest populations. Furthermore, to capture the breadth of potential impacts, these studies could consider a range of scenarios, not just the highest or worst-case scenarios.

There is a gap in research characterizing how climate-related health impacts differ based on local population-specific characteristics and shared realities, particularly across the urban–rural gradient and multiple Tribal Nations and as a result of increasing immigration. This is particularly true for specific health outcomes (e.g., mental health) and health determinants (e.g., livelihood). Such information would be useful for developing targeted, effective intervention strategies that address existing inequities and historical racism.

The literature currently lacks studies specific to the Midwest that attempt to quantify the cost burden associated with climate impacts on health and key health determinants like livelihood or housing security. Thus, there is uncertainty about how much climate change impacts are costing Midwest communities in terms of injury, disease, job loss, property damage, healthcare utilization, and more.

Certain emerging topics for climate and health in the Midwest, including climate-driven migration and concerns for people with disabilities, were not covered due to a lack of literature specific to the Midwest region. Thus, it is uncertain what the attending health impacts may be related to these topics and how they may be distributed throughout a community.

Description of Confidence and Likelihood

There is *high confidence* and it is *very likely* that climate change will impact the health and well-being of individuals and communities in the Midwest across a wide range of exposure pathways. Literature shows that these pathways include extreme events, such as flooding, drought, heatwaves, and wildfires, that all pose an increasing risk to physical and mental health by direct exposure. Studies show that indirect exposure through degrading air and drinking water quality threatens livelihoods and strains essential health and emergency-related services. An individual's exposure and sensitivity to climate change is *very likely* influenced by preexisting health conditions, income, race and ethnicity, age, and access to resources (*high confidence*). Evidence illustrates that health disparities tied to racism and income inequality are *likely* linked to an inequitable distribution of climate-related health outcomes. Actions and investments to reduce climate-related health and community impacts can yield multiple health benefits while helping to advance more equitable climate adaptation (*high confidence*).

Key Message 24.4

Green Infrastructure and Investment Solutions Can Address Costly Climate Change Impacts

Description of Evidence Base

Based on numerous independent analyses, much of the infrastructure of the Midwest is aging, and repairing this infrastructure will come at a significant cost (e.g., American Society of Civil Engineers Report Card for America's Infrastructure).[248] These costs require new forms of financing, data, and expertise, much of which is just emerging. The infrastructure deficit in the Midwest is articulated through academic literature and practitioner resources and research,[236,248] all demonstrating that the infrastructure of the Midwest is aging and that repairing it will come at a significant cost. These costs require new forms of financing, data, and expertise, much of which are just emerging.[236] There is strong evidence showing that increasing storm damages to infrastructure across the Midwest disproportionately impact people with low income and BIPOC populations.[258] Numerous studies of social vulnerability and adaptive capacity demonstrate that individuals with lower vulnerability and higher adaptive capacity are better able to prepare for and recover from disaster.

Major Uncertainties and Research Gaps

Storm damages not captured through disaster declarations are difficult to identify, and midsize disasters are difficult to quantify. One method for quantifying these midsize disasters could be to report on the total times states in the Midwest declare a state of emergency in response to a weather- or climate-related event. There is a gap in aggregated and standardized reporting of state-declared disaster events and related losses. Another approach could be to calculate insurance losses as reported by private insurance companies with holdings in the region. State-level data and private insurance datasets are accessible but require analysis and synthesis to be usable by decision-makers. The US Billion-Dollar Weather and Climate Disasters report, developed by NOAA's National Centers for Environmental Information, has become a common way to understand the increasing cost incurred by climate change and related extreme events. However, many smaller-scale yet damaging storm events occur annually and lead to damage or destroyed infrastructure, loss of life, and harm to the health and well-being of people in the Midwest. One measure of these events is through the National Flood Insurance Program database. Tracking these events and the related economic impact could enable more effective and equitable distribution of resources before and following extreme storms.

Climate migration is an area of uncertainty, yet information is highly sought within academic and public spheres. Literature and resources on community relocation within the region exist, but literature and evidence on climate-induced migration of people moving into the region is not currently available.

Description of Confidence and Likelihood

There is strong evidence that climate change *likely* threatens built infrastructure, especially if a heavy dependence on conventional road transportation continues. Uncertainty about the modes of transportation that will exist in the future and uncertain trends toward electrification result in an assignment of *medium confidence*. More certain are the impacts from increased precipitation extremes and transitions between wet and dry conditions on riverine and Great Lakes environments (*likely*, *high confidence*). The emergence of new investments offers alternative methods toward development, but volatility in the economy leaves some uncertainty whether more communities and local businesses will embrace these tools (*medium confidence*).

Key Message 24.5

Managing Extremes Is Necessary to Minimize Impacts on Water Quality and Quantity

Description of Evidence Base

There is strong evidence that the Midwest and Great Lakes water is and will continue to be impacted by climate change, with associated adverse effects for both human society and ecosystems.[267] The evidence for change is supported by the trends in temperature, precipitation, runoff, and evapotranspiration.[268] Further, reasonably good climate-based scenario model performance in the past provides confidence in those predictions going forward.

The evidence and research were more consistent for water quantity and water management than for water quality.[280,281] This is due, in part, to the more complex nature of water quality. The biggest areas for lack of agreement were in harmful algal blooms (HABs) and how global climate scenario-based models deal with the regional representation of the Great Lakes.

Major Uncertainties and Research Gaps

The lack of robust model simulations of how the Great Lakes physically operate is a major gap and uncertainty. Climate processes in the Great Lakes region are difficult to simulate due to the complexity of lake–land–atmosphere interactions.[6] Even the most sophisticated climate models for the Great Lakes region have deficient physical representations of the key hydrological components that make up a lake's net basin supply (i.e., precipitation, evaporation, and runoff).[6] Therefore, high levels of uncertainty are associated with future lake-level projections that are based on simulated changes to these hydrological components. However, higher variability in future water levels is anticipated, which will impact the entire ecosystem (KM 24.2), ports (KM 24.4), and coastlines.[284,301] Better physical representation of the Great Lakes would enhance confidence in how increases in the water temperatures of the lakes (both surface and deep lake) could impact the ecosystem.

HAB research across the Midwest and Great Lakes is conflicting and limited.[280,281] While research has been more conclusive in the Great Lakes with increasing HAB severity, research has been inconclusive in the Midwest as to whether HAB severity has been increasing, remaining constant, or decreasing. Connections to agricultural tiling and septic systems and their impacts on water bodies are additional knowledge and data gaps.

Temperature, precipitation, and runoff research is much more comprehensive in the Midwest than streamflow research.[268] There is limited available work on large basin–scale streamflow to assess climate impacts. The Ohio River Basin Climate Change project, by the US Army Corps of Engineers and NOAA,[240] is one of the US's largest and most comprehensive climate change–related projects on water quantity, quality, and management for streamflows on medium- to larger-scale systems. A similar Midwest project by NOAA's North Central River Forecast Center and the University of Minnesota is underway for the upper Mississippi River basin. More large-scale hydrologic projects, including in the Missouri River basin and Great Lakes, would aid in understanding large-scale streamflow changes and projected impacts. The absence of more such projects limits the ability to have higher confidence in some areas of water quantity, quality, and management. Combining Coupled Model Intercomparison Project Phase 5 with the Variable Infiltration Capacity hydrology modeling is a step in the right direction.

Description of Confidence and Likelihood

Confidence and likelihood were assigned based on the consistency of the information in trends and research combined with strengths and weaknesses in the climate scenario models. For the Midwest and Great Lakes, there is consistent information to support *high confidence* for air temperatures, precipitation, and runoff trends and projections and the impacts to water quantity, water quality, water management practices, ecosystem health, food production, and recreation.[15] Based on literature and projections, it is *likely* and there is *high confidence* that increases in runoff (in all seasons but summer, where some decreases are projected), drought, and flooding will adversely affect ecosystems through increased erosion and the expansion of invasive species. This applies to enhanced erosion and expansion of invasive species. For harmful algal blooms (HABs), the literature and projections support *high confidence* for continued HABs in the Great Lakes. For the Midwest, confidence is lower that increased temperatures and precipitation and runoff will continue to lead to variable changes in HAB events (increasing, decreasing, or remaining unchanged). This will *likely* result in continued adverse impacts to water quality and ecosystems. There are numerous examples where federal and state agencies along with nongovernmental organizations are collaborating on adaptation efforts related to water in the Midwest (*high confidence*).

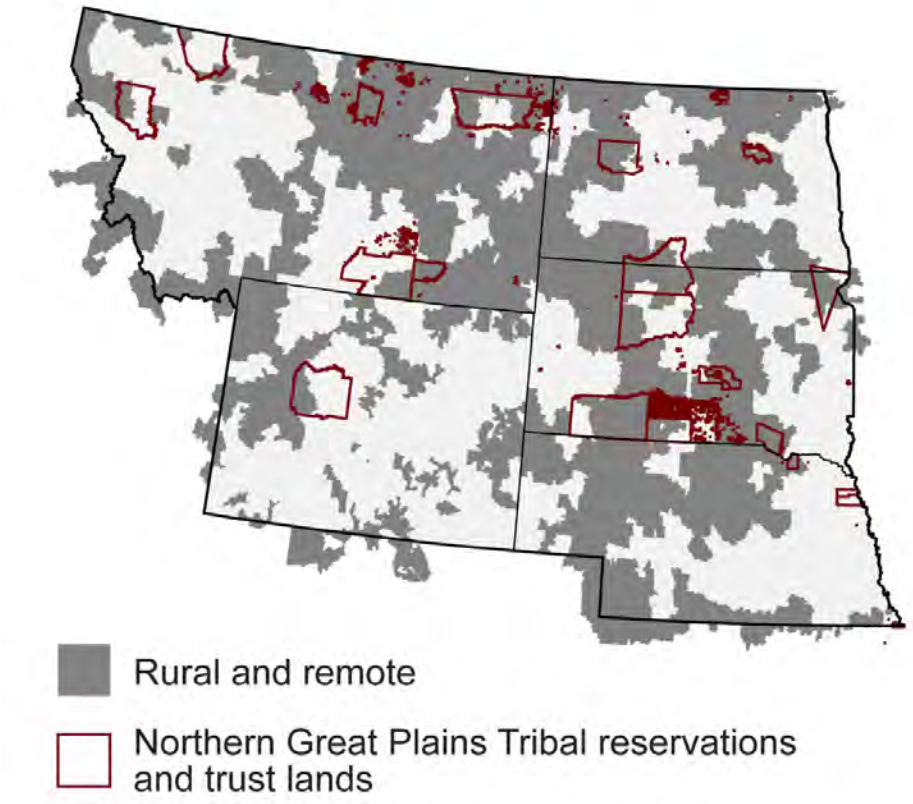
Introduction

The Northern Great Plains region, which includes Montana, Nebraska, North Dakota, South Dakota, and Wyoming (Figure 25.1), has a wealth of natural resources supporting economies, sense of place, and leisure activities. Climate change impacts on individuals and communities will differ, and it is critical to consider equity dimensions (Ch. 20). Economic dependence on crops, rangelands, and recreation makes residents with land-based livelihoods vulnerable to climate-related changes in weather, as well as flows of water, nutrients, and wildlife across the landscape.[1,2,3] This region is largely rural, and its intact natural areas, farms, and wildlands serve as habitat for resident and migrating species, which are threatened by changing water scarcity. The region is an energy and food exporter and vulnerable to policy decisions and markets outside the region. Historical processes may lead to unequal distribution of harms, with Indigenous communities, service and energy workers, and rural residents more sensitive to impacts. Values related to place, community, and stewardship are strong. Residents of small towns express strong place attachment in comparison with their urban counterparts.[4] The region's population grew by 10% between 2008 and 2020. Ten metropolitan counties accounted for two-thirds of growth, while 75% of the region's rural counties lost population.[5] Among rural counties, energy-dependent and tourism-focused counties both grew by 14%,[6] and farm-dependent communities experienced a 3% decline in population over the same period.[7,8] An indication that more people are willing to move to the region due to climate conditions was the influx of remote workers from large cities during the COVID-19 pandemic.[9]

This region also has many vibrant Indigenous communities with a rich cultural heritage (Figure 25.1). There is increased environmental action from Indigenous communities to protect waters and lands, to navigate climate change, and to maintain cultural continuity.[10] Culturally appropriate adaptation strategies, such as the restoration of buffalo, which serve a valuable ecological role and reestablish historic relationships to landscapes, are rooted in this region.[11] "Buffalo" is the preferred term of Indigenous communities based on their culture and history; this term is used in reference to Indigenous actions while acknowledging that the scientific name of the species is American bison (*Bison bison*). Although the share of the non-White population remains small in absolute numbers, the region is becoming more culturally diverse. The Indigenous and Hispanic populations grew by 20% and 42%, respectively, between 2010 and 2019, and in 2019, Indigenous and Hispanic populations accounted for 4% and 7% of the total population.[8]

Tribal Lands and Rurality Measures

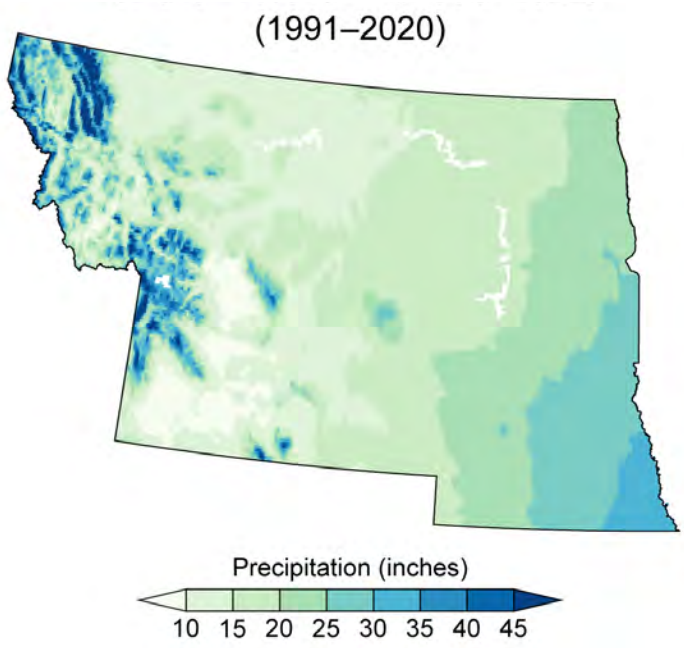


Rural areas, including those controlled by Indigenous Peoples, are often under-resourced and therefore less resilient to climate change.

Figure 25.1. Tribal reservations and American Indian trust lands (red outlines) overlap rural areas (dark gray; as defined by the USDA) across the Northern Great Plains. Rural and historically marginalized communities are often under-resourced and lack capacity to prepare for and recover from climate-driven natural disasters, making large portions of the Northern Great Plains less resilient to climate change.[12] White sections represent areas that fail to meet the criteria for "remote from urban" as defined by the USDA.[13] Figure credit: University of Wyoming, Center for American Progress, NOAA NCEI, and CISESS NC.

The Northern Great Plains region is known for its climate extremes and variability, but climate change is intensifying these characteristics.[14,15,16,17,18] The region has strong east–west precipitation (Figure 25.2) and north–south temperature gradients (Figure 25.3). Moving east to west across the region, the landscape becomes drier and elevation increases, forming three distinct areas: the humid eastern plains, semiarid high plains, and mountainous west. This complexity makes it challenging to summarize climate impacts across the region, but there are some common changes. Climate extremes in this region are expected to continue, compounded by climate change (KM 25.1). Human and ecological health will be impacted by these compounding hazards (KM 25.2). Human communities reflect the dependence on natural resources, historical policy legacies, and market forces that left a patchwork of land ownership and use (such as crop versus range, energy development, and recreation; Figure 25.8), and these livelihoods are at risk (KM 25.3). Climate change response will involve navigating complex tensions and trade-offs (KM 25.4), but communities are already building their capacity to adapt and transform (KM 25.5).

Average Precipitation for the Northern Great Plains



The region has distinct east–west precipitation gradients.

Figure 25.2. The map shows annual precipitation averaged over 1991–2020. Distinct precipitation gradients are evident from east to west and with elevation. These gradients highlight the complexity of the climate across the Northern Great Plains. White areas are large water bodies. Figure credit: USGS, University of Wyoming, NOAA NCEI, and CISESS NC.

Key Message 25.1

Climate Change Is Compounding the Impacts of Extreme Events

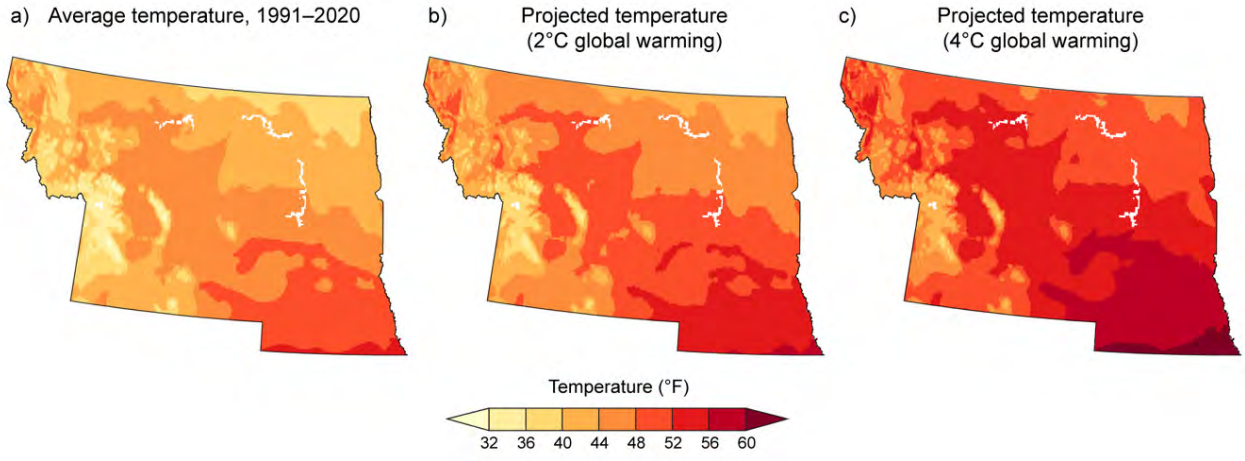
The Northern Great Plains region is experiencing unprecedented extremes related to changes in climate, including severe droughts (*likely*, *high confidence*), increases in hail frequency and size (*medium confidence*), floods (*very likely*, *high confidence*), and wildfire (*likely*, *high confidence*). Rising temperatures across the region are expected to lead to increased evapotranspiration (*very likely*, *very high confidence*), as well as greater variability in precipitation (*very likely*, *high confidence*).

Temperatures and Precipitation

Given the frequency of extremes and weather variability in the region, it is challenging to quantify long-term climate change trends. Even so, significant temperature trends and projections are clear (Figure 25.3). Since 1900, annual average temperature has increased in the region by 1.6°–2.6°F, with the largest increase in North Dakota and the smallest increase in southern Nebraska. Warming has occurred in all seasons but is most pronounced in winter. Summers have warmed little in North Dakota, South Dakota, and Nebraska. However, warm nights (minimum temperature of 70°F or higher), which were once rare, have become more common in Montana and Wyoming. The region has experienced fewer very cold days (maximum temperature of 0°F or lower) than the long-term average (1900–2020) for several decades. For

instance, the number of very cold days has been below the long-term average in Montana since 1985, in Nebraska since 1990, and in Wyoming, North Dakota, and South Dakota since 2000.[14,15,16,17,18] Decreasing snowpack will alter surface water availability for irrigation and may increase pressure on groundwater resources.[3,19] Overall aridity has increased and is projected to continue to do so because of increases in potential evapotranspiration, suggesting that the demarcation line between the humid East and arid West, traditionally defined by the 100th meridian, is moving eastward.[20,21]

Temperature for the Northern Great Plains



Distinctive gradients of temperature will hold with projected warming.

Figure 25.3. The maps show temperature averages for 1991–2020 (**a**) and projected temperature for global warming of 2°C (3.6°F; **b**) and 4°C (7.2°F; **c**) above preindustrial levels for the Northern Great Plains region. Current and projected values demonstrate distinctive gradients of temperature from southeast to northwest, with implications for climate impacts and effective adaptation. White areas are large water bodies. Figure credit: USGS, NOAA NCEI, CISESS NC, and University of Wyoming. See figure metadata for additional contributors.

All states in the Northern Great Plains region recorded their wettest five-year period between 1995 and 2019.[14,15,16,17,18] Total annual precipitation will be relatively stable across the region (Figure 4.3), but shifts in the form and timing of precipitation are expected. More intense precipitation events highlighting the projected increased variability in precipitation are expected to occur in all seasons, especially in the spring (Figure 2.12).[22] Temporal and spatial variability continues to be a dominant factor with precipitation and temperature.

Much of the runoff in the Northern Great Plains region contributes to the Missouri River and eventually the Gulf of Mexico, but portions contribute to the Columbia River, Colorado River, and Red River of the North basins. Much of the increasing streamflow in North Dakota shown in Figure 25.4 occurs in the Red River of the North basin and has prompted an approximately $3.2 billion (in 2022 dollars) infrastructure project to divert flood water around Fargo, North Dakota, and Moorhead, Minnesota.[23] The upper Colorado River basin (Colorado, Wyoming, Utah, and New Mexico), with headwaters in the western Northern Great Plains region, has been experiencing extensive drought for the last 20 years. Flows in the upper Colorado River basin, which account for about 90% of the streamflow of the entire basin,[24] have decreased over the past 20 years.[25,26] Increases in evaporative demand (the loss of water from Earth's surface to the atmosphere; Figure 25.5) have decreased runoff efficiencies, meaning that less rain and melted snow end up reaching the streams that feed the Colorado River.[27] Model-based analysis shows that continued warming is expected to further reduce flows in the upper Colorado River basin.[26]

Hail

The region is prone to damaging hailstorms; southeastern Wyoming and the southwestern part of the Nebraska Panhandle lie in "hail alley," the most hail-prone area in the United States.[17,18] Changes in low-level moisture, convective instability, melting level height, and wind shear will create shifts in hail occurrence.[28] From 1979 to 2017, the number of days favorable to significant (2 inches or greater diameter) hail in the central and eastern United States increased by 2 to 4 days each year.[29]

Research on the response of severe convection to climate change has focused on a very high scenario (RCP8.5).[30,31,32,33] Hail size, frequency of large hail, and length of hail season are projected to increase through the rest of this century in the Northern Great Plains.[33] By 2071–2100, under a very high scenario (RCP8.5), projections for the Northern Great Plains show a 27% increase in moderate-size (0.79–1.4 inches) hail days, a 49% increase in large (1.4–2.0 inches) hail days, and a 302% increase in very large (2 inches and larger) hail days, with increases in hail coverage of 73%, 157%, and 882% for moderate, large, and very large hail, respectively.[33] Projections also indicate a lengthened hail season.[33] The largest increases in hail risk anywhere in the United States are in this region and in July.[33] Projections by late this century using the SRES (Special Report Emissions Scenarios) A2 scenario (a scenario with increasing greenhouse gas emissions, similar to those in RCP8.5) indicate more hail days and an increase in the potential size, with a correspondent increase in accumulated kinetic energy and damage potential.[34] Comparing intermediate (RCP4.5) and very high (RCP8.5) scenario projections for severe convection indicates that the projected trends for RCP4.5 are in the same direction with lower amplitude compared to RCP8.5.[35]

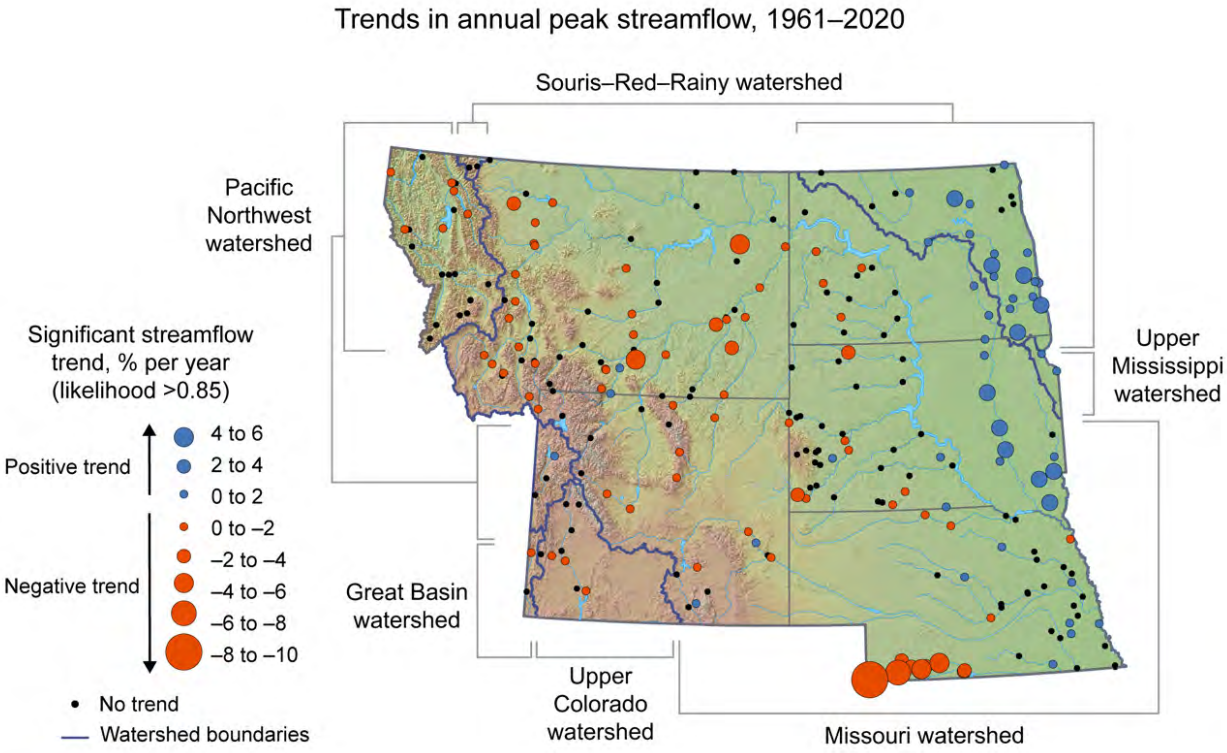
Flooding

Precipitation changes do not have a one-to-one relation with flooding. Many factors influence floods, including short- and long-term antecedent moisture conditions, presence of frozen soils, snowpack accumulation, rain-on-snow events, storm tracks, and rainfall rates.[36,37,38,39]

The Missouri River transects the region through 10 US states and 28 Tribal territories and is emblematic of the complex intergovernmental relations that will become increasingly important under climate change.[40] Record floods along the Missouri River and its tributaries in 2011 and 2019 caused evacuations, cost billions in damages,[41] and created interstate closures. Research suggests that recent large floods were caused by natural variability within the system;[42] however, model simulations suggest that climate change will reduce runoff in the upper Missouri basin.

Trends in annual peak streamflow, a proxy for flooding, differ across the 100th meridian divide (Figure 25.4). Observations show that annual peak streamflow is decreasing in the west and increasing in the east.[43] With few exceptions, the eastern Dakotas are an area of increasing peak streamflow (and flooding), while the western Dakotas, Montana, and Wyoming have decreasing peak streamflow. With 2° to 4°C (3.6° to 7.2°F) of global warming, the Northern Great Plains would expect to see some of the highest increases in annual flooding damage costs in the contiguous US due to climate change.[44]

Water Resource Regions and Rivers



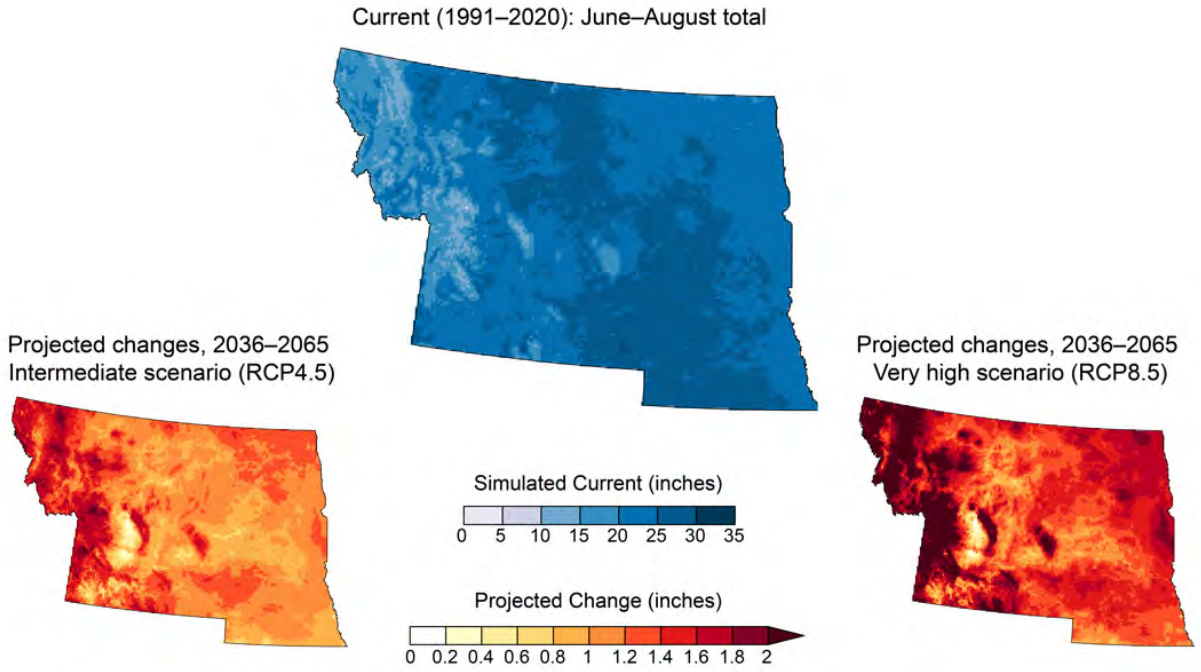
Annual peak streamflow—a proxy for flooding—has been rising in eastern portions of the region and declining in the west.

Figure 25.4. This map of the water resource regions and rivers within the region shows distinct east–west differences in trends in annual peak streamflow for 1961–2020, expressed as percent per year, where the size of the dot is relative to the size of the trend. Red dots are downward trends, and blue dots are upward trends. A likelihood-based approach is used to report these trend results. When a trend is identified, the trend likelihood value (likelihood = 1 – p-value/2) associated with the trend is between 0.85 and 1.0. In other words, the chance of the trend occurring in the specified direction is at least 85 out of 100. Smaller black dots are sites for which there were sufficient data for trend analysis but likelihood was less than 0.85; that is, these sites do not exhibit a substantial trend in either direction. Figure credit: USGS, NOAA NCEI, and CISESS NC.

Drought

Drought is projected to increase in the region, with localized droughts increasing by 2040 and more widespread regional droughts by 2070, under intermediate (RCP4.5), high (RCP6.0), and very high (RCP8.5) scenarios across wet or dry global climate models.[22,45] After precipitation, the most significant component of the water budget is evapotranspiration—the moisture transfer from Earth's surface and plants to the atmosphere.[46] Projected warming is expected to increase evapotranspiration (Figure 25.5), which may lead to drier soils later in the growing season (Figure 25.6).[47,48,49] Summer drought will be more probable than spring drought.[22,50] Multiple future climate scenarios indicate future increases in moderate, severe, and extreme drought, occurring approximately 10% and 20% more frequently by 2050 and 2100, respectively.[45] Recent droughts in the upper Missouri River basin between 2000 and 2010 were the most severe in the instrumental record,[51] and flash droughts are a growing concern.[52,53]

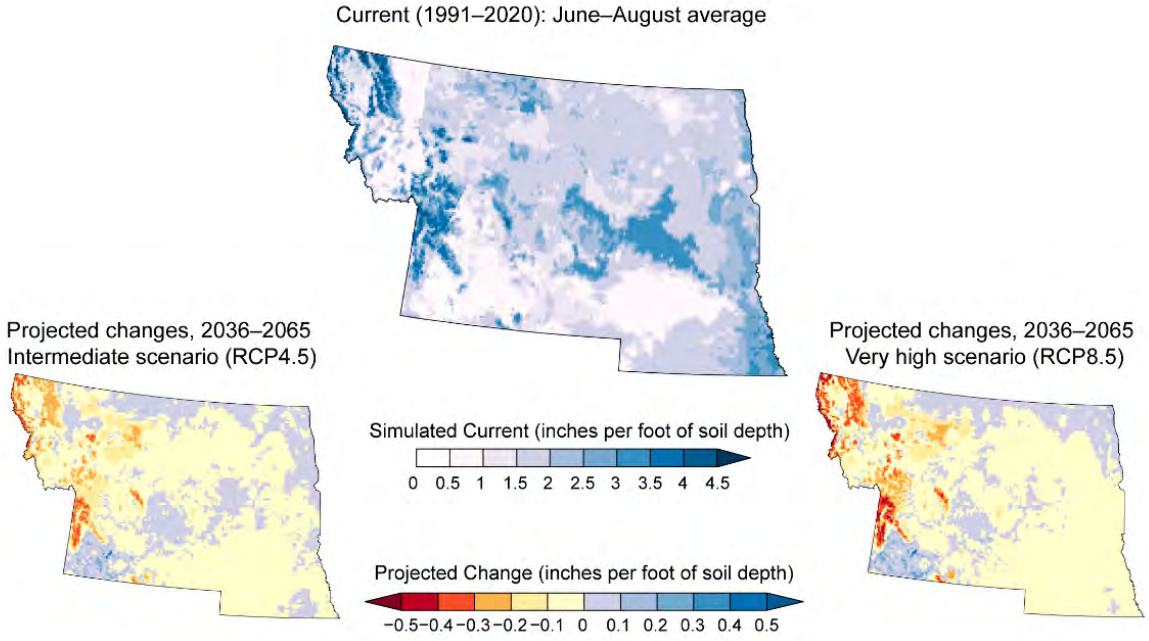
Current and Projected Potential Evapotranspiration



Warming is expected to increase evapotranspiration.

Figure 25.5. Figure shows (**center**) simulated current evapotranspiration and its projected change for the summer months under (**left**) intermediate and (**right**) very high scenarios. Data presented were obtained from Variable Infiltration Capacity models driven by the Coupled Model Intercomparison Project Phase 5 and Localized Constructed Analogs downscaling methods. Potential evaporative demands in the summer months (June, July, and August) increase regionally, especially in western areas under moderate climate change, and in both western and eastern areas under severe climate change. An increase in potential evapotranspiration typically drives a decrease in surface soil moisture (4-inch depth; Figure 25.6). Figure credit: USDA Forest Service, NOAA NCEI, and CISESS NC. See figure metadata for additional contributors.

Current and Projected Soil Moisture



Warming may not always lead to declines in soil moisture that would cause water stress in crops and natural plants.

Figure 25.6. Figure shows (**center**) simulated current soil moisture and its projected change for the summer months under (**left**) intermediate and (**right**) very high scenarios. Data presented were obtained from Variable Infiltration Capacity models driven by the Coupled Model Intercomparison Project Phase 5 and Localized Constructed Analogs downscaling methods. Soil moisture is expected to decrease slightly throughout the region in the summer months, with the largest decreases in the western mountain ranges of Montana. An increase in southwestern Wyoming is projected under both intermediate and very high scenarios. Snow water equivalent is decreasing at higher elevations in the Northern Great Plains (Figure 4.5) and can contribute to lower soil moisture in these areas. Declines in soil moisture can lead to crop, forest, and rangeland plant water stress, reduce plant growth, and increase ecosystems' susceptibility to fire. Figure credit: USDA Forest Service, NOAA NCEI, and CISESS NC. See figure metadata for additional contributors.

Wildfire

Driven by increased temperature and decreased relative humidity, fire potential in this region is projected to increase under future climate change (HadCM3-HRM3 model), especially in summer and autumn, with fire seasons becoming longer.[54] Increased evapotranspiration and drought risk raise the probability of large fire occurrence.[55,56] The number of large grassland wildfires in the four semiarid ecoregional grasslands of the Northern Great Plains increased by 213%, from 128 between 1985 and 1995 to 273 between 2005 and 2014, with total area burned increasing in the western ecoregions of the region by 350% but decreasing in eastern ecoregions by 75% or more.[57] Wildfire numbers and fire-season length increased from the 1970s to the 2000s by 889% and 85 days, respectively, in western Montana and Wyoming forests, with most ignited by lightning strikes rather than humans.[58] Historically, snow cover prevented winter wildfires and increased fuel moisture conditions during snowmelt followed by spring precipitation.[59,60] However, early spring snowmelt has been correlated with increased fire activity.[58] From 1950 to 2010, the number of snow-cover days declined within the region,[60] increasing wildfire activity due to drying fuels, which can lead to changes in flash flooding and debris flow (Focus on Western Wildfires).

Key Message 25.2

Human and Ecological Health Face Rising Threats from Climate-Related Hazards

Climate-related hazards, such as drought, wildfire, and flooding, are already harming the physical, mental, and spiritual health of Northern Great Plains region residents (*virtually certain*, *high confidence*), as well as the ecology of the region (*very likely*, *medium confidence*). As the climate continues to change, it is expected to have increasing and cascading negative effects on human health and on the lands, waters, and species on which people depend (*very likely*, *medium confidence*).

Mental Health

Climate change adversely affects mental and spiritual health in multiple ways (Ch. 15).[61,62] Although this issue affects the entire country, it is especially relevant in the Northern Great Plains, where three states are among the top 10 in highest suicide rates per capita in the Nation.[63] Suicide rates are particularly high in rural and Indigenous populations,[64] in part because of remoteness from care and the limited number of mental health professionals.[65,66] Based on geographically broad-based studies, climate change is projected to amplify these risks.[67,68] Climate anxiety, also called eco-anxiety (a feeling of doom about future climate change), is already prominent among farmers and ranchers in the region.[69] Solastalgia—the distress specifically caused by environmental change while still in a home environment[70,71]—is indicative of more subtle but potentially wider-reaching mental health impacts. Solastalgia is most often associated with Indigenous communities, who share collective ancestral ties to the lands and natural resources where they live or previously lived and which are inextricably linked to their identities, cultures, and livelihoods, as well as their physical and spiritual well-being.[72] However, solastalgia can also affect others who are connected to the land, such as ranchers and farmers.[73]

Direct impacts such as crop failure, increased disease, and biodiversity loss can lead to increased loss of Traditional Knowledge and language, further influencing the mental health of Indigenous Peoples.[61,74] Despair related to the loss of environmental, cultural, and human health is widespread among Crow Tribal elders, adversely affecting mental and spiritual health, and is exacerbated by a sense of inability to address the root causes of climate change.[75,76]

Physical Health

Climate change is impacting the physical health of the region's inhabitants in a number of ways. Wildfire is projected to increase in the region (KM 25.1), with correspondent health and property implications (Chs. 14, 15; Focus on Western Wildfires).[61] One study suggests that although the total number of premature deaths attributable to wildfire smoke is higher in states with greater population density, Montana has the highest per capita rate of such deaths in the country.[77] In addition, heat is responsible for more climate-related deaths than any other factor in the United States.[78] Although the Northern Great Plains region lacks the extreme temperature increases experienced in some other regions, people in this region are still at risk given the large number of outdoor workers and recreationists.[79] Rising temperatures, as well as other climate impacts, are expected to increase the risk of some vector-borne diseases, such as West Nile virus.[80,81,82] Flood risk patterns in the United States are inequitable on a county basis, with some of the counties in this region at increased risk, including some that encompass or are adjacent to Tribal reservations.[83] Shifts in precipitation and increased flooding (KM 25.1) are expected to raise the risk of water-borne diseases such as *Campylobacter* infection.[84]

Compound Health Impacts of Climate Events

Multiple climate pressures frequently act simultaneously, leading to compounding health-related outcomes (Ch. 15).[61,85,86] The impacts of floods resulting from earlier snowmelt combined with more intense precipitation events can be worsened by loss of ground cover from past wildfires,[87] putting people at risk of water-borne diseases, trauma and increased mental health issues, and economic losses. Wildfires are more common during hotter months when drought is more common,[55,56] exposing people to compounding risks and stress from smoke, heat, and poor water quality.[88,89]

Ecological Health

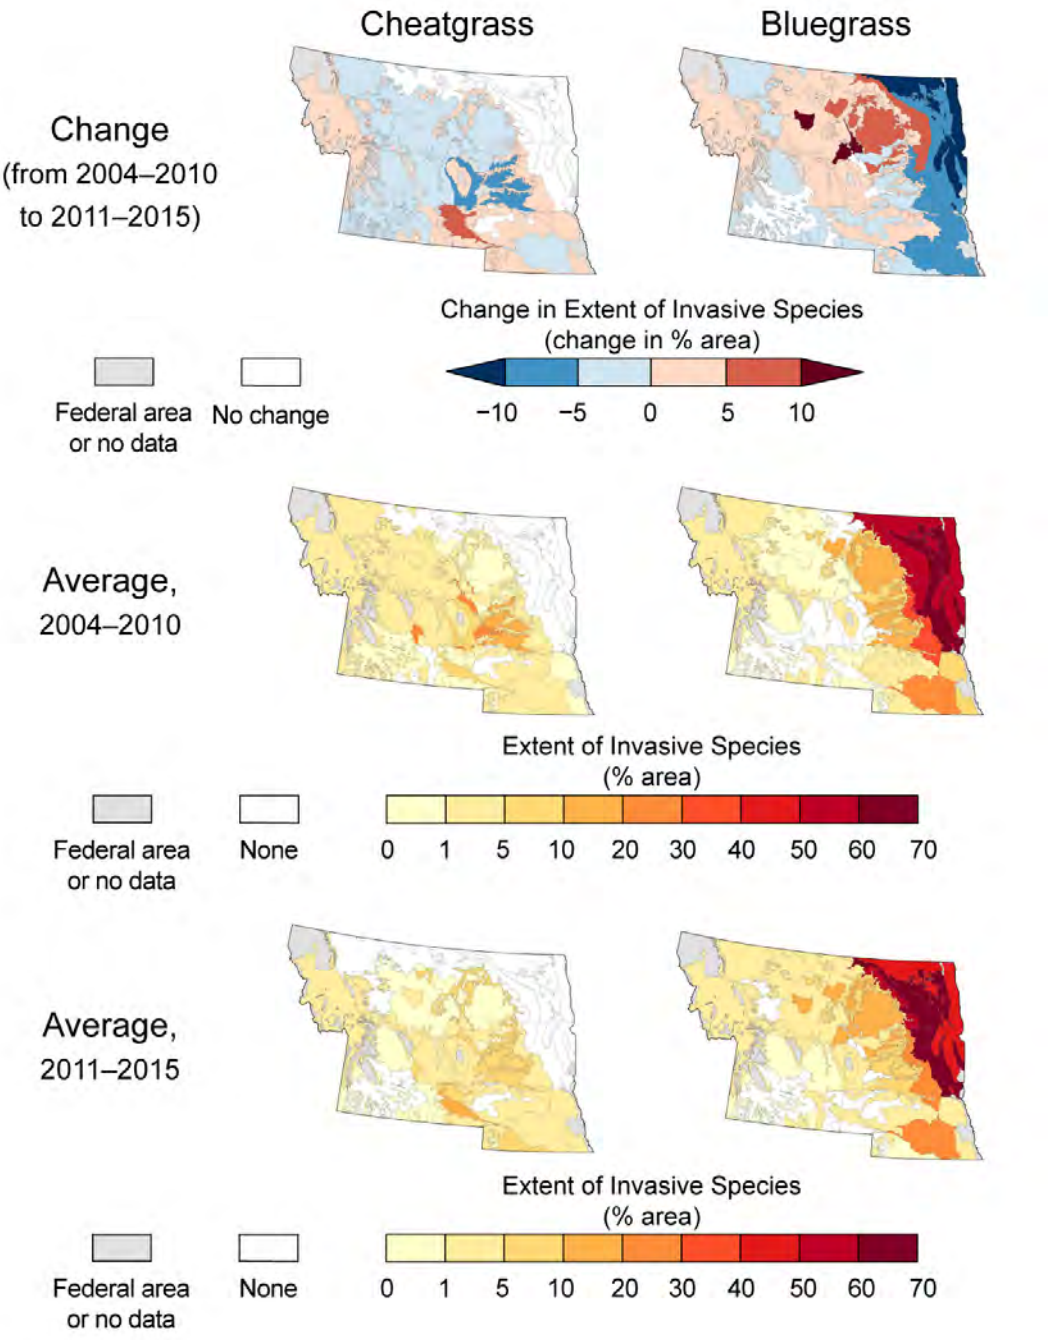
Water Quality

Excess contributions of nutrients, such as nitrogen and phosphorus from agricultural runoff or point sources such as wastewater treatment plants, can cause water quality issues, which are expected to be exacerbated by climate change.[90,91] Nutrient loads (the total amount of a nutrient transported past a single location over a set period of time) can increase after droughts, when sediment is flushed in subsequent runoff events.[92] Nutrient runoff from agricultural land spikes after heavy rain and contributes to harmful algal blooms and transport of nutrients to the Gulf of Mexico (KM 25.5).[93,94,95] Climate change has long been hypothesized as a driver of harmful algal blooms;[96] supporting these hypotheses with observations has been challenging because of gaps in monitoring, lack of long-term algae data, and changes in laboratory and remote-sensing methods.[97,98]

Cascading Impacts to Biodiversity Loss

Climate change compounds existing threats to biodiversity (Ch. 8). Within the Northern Great Plains, conversion of perennial grasslands to monocultures of annual crops results in a loss of biodiversity.[99] Invasive species are also a contributor to biodiversity loss in the region,[100,101] and the dominant invasive species of concern varies from east to west (Figure 25.7). The region is a hotspot for grassland bird diversity and encompasses the entire breeding season range for many of the most vulnerable species;[102,103] based on projections under a scenario with 5.4°F (3.0°C) warming above preindustrial levels, more than 80% of grassland bird species will be vulnerable to climate-related threats during the breeding season.[104] Both native pollinators and honeybees are important components of the region's ecosystems. The region supports approximately 40% of US honeybee colonies in the summer.[105] Over the last 15 years, pollinators have been experiencing declines.[106] Although not directly linked to climate change, changes in land-use patterns related to biofuel policies and loss of Conservation Reserve Program (CRP) lands are potentially contributing to these declines.[105,107] The CRP program pays farmers to take marginal land out of agricultural production for 10 years and plant perennial cover to reduce soil erosion and provide other ecosystem benefits. Recent modeling, however, indicates that targeting where CRP lands are planted on the landscape could improve the benefits to pollinators.[108] Finally, natural resource managers have identified a number of management strategies to help reduce biodiversity loss in the face of climate change, but for many taxa and ecological communities, there are still knowledge gaps.[109,110]

Invasive Species as Bioindicators of Ecological Condition



Invasive cool-season grasses are reducing biodiversity in the Northern Great Plains.

Figure 25.7. Acreage in the Northern Great Plains region where at least 50% of the soil surface is covered by two representative invasive plant species: cheatgrass (*Bromus tectorum*; **left**) in the western part of the region, and Kentucky bluegrass or Canada bluegrass (*Poa pratensis* or *Poa compressa*; **right**) in the eastern part of the region. The figure shows acreage for 2004–2010 (**center**) and 2011–2015 (**bottom**), as well as the change in extent of invasion between those two periods (**top**). These invasive grasses already pose a threat to the biodiversity of the region, and climate change is predicted to increase invasive species challenges for this region. Figure credits: (center left, bottom left, center right, bottom right) adapted from NRCS 2018;[111] (top left, top right) The Nature Conservancy, NOAA NCEI, and CISESS NC.

Key Message 25.3

Resource- and Land-Based Livelihoods Are at Risk

The Northern Great Plains region is heavily reliant on agriculture and resource-based economies, placing livelihoods at risk from the impacts of climate change and related policy. Agriculture and recreation will see some positive effects but primarily negative effects related to changing temperature and precipitation regimes (*likely*, *medium confidence*). Energy-sector livelihoods will be affected as emissions-reductions policies drive shifts away from fossil fuel sources (*likely*, *high confidence*). Climate change is expected to test the adaptive resilience of the region's residents, in particular rural, Indigenous, and low-income immigrant populations (*likely*, *medium confidence*).

Food and Agriculture

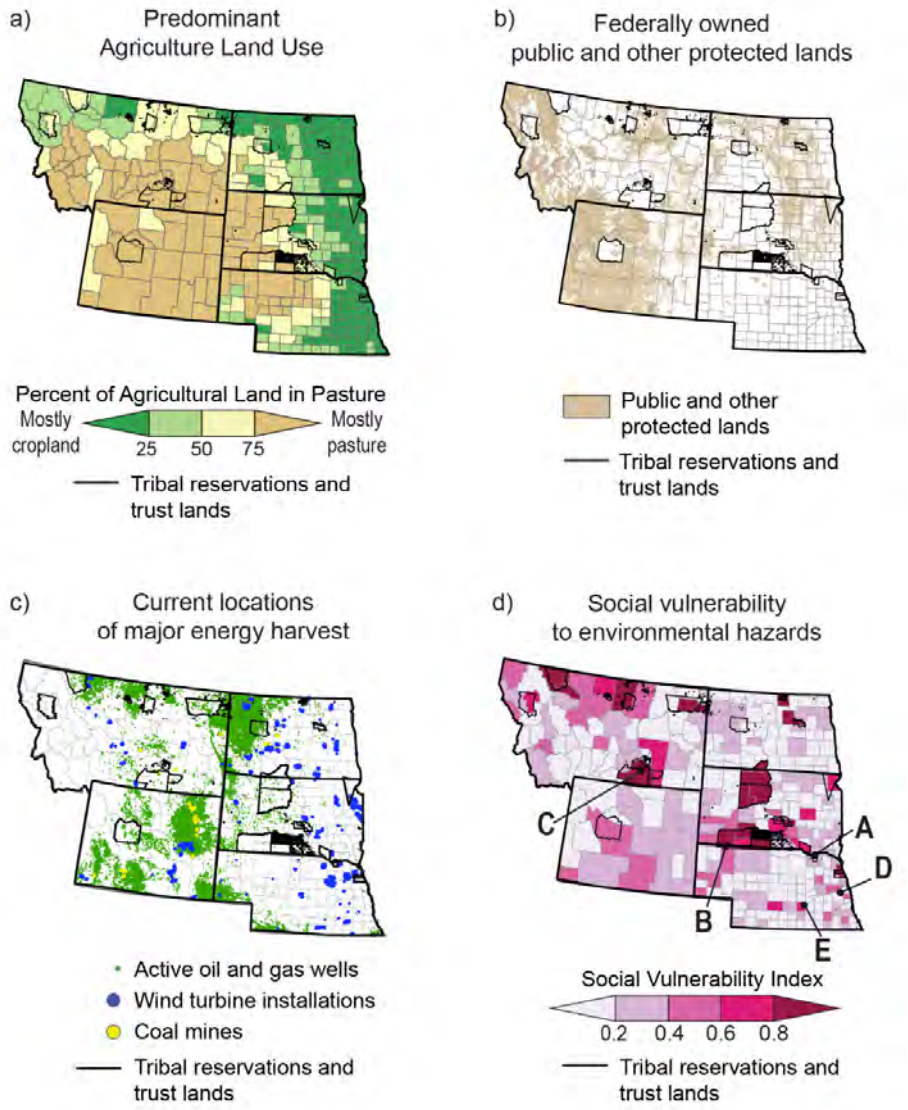
Farming (referring to all forms of agricultural production, including livestock operations) accounts for 6% of total earnings in the region, compared to 0.4% of total earnings nationally.[112] Although growing seasons and frost-free periods are lengthening,[113,114] other factors may stress crop production.[49] Negative crop yield impacts are anticipated from rising temperatures, which increase the potential for heat and moisture stress during reproductive periods, as well as the potential for increased weed competition and pest expansion.[3] Although row crop agriculture generally occurs where greater average annual precipitation occurs (Figures 25.2, 25.8a), farmers are expanding and intensifying croplands into less productive lands in the region[99,115,116] as climate change alters growing conditions. Although crop yield decline from increased evapotranspiration may be somewhat offset by soil moisture trends, soil moisture is projected to slightly decline on an annual basis across much of the region (KM 25.1).[117,118] Overwintering crops like winter wheat are expected to benefit from reduced exposure to frost days under climate change, but reduced ground insulation from declining snow cover may offset some of this gain.[119] Additionally, higher carbon dioxide concentrations are expected to benefit the productivity of many crops.[120]

The net effect of climate change on specific crop yields is uncertain and will depend on interacting effects of temperature, moisture, carbon dioxide, and ozone, as well as adaptation through shifts in cultivars, crop mix, and management practices.[120,121,122] For example, climate change was listed as a primary challenge to both dryland and irrigated agriculture in the 2022 Blackfeet Agricultural Resource Management Plan (ARMP), due to earlier snowmelt, increased evapotranspiration, and less water available for irrigation. Recent extreme events indicate potential future impacts to livelihoods of individuals throughout the agricultural value chain.[123] Climate change negatively impacts the ability of regional Indigenous communities to grow and use traditional foods, medicines, and plants due to species movements and shifts in growing and harvesting seasons. Two significant examples are the Lakota staples wild turnips and chokecherries.[124,125] In 2017, above-normal temperatures in late summer and fall delayed the harvest of berries and medicinal plants.[126]

Northern Great Plains rangeland productivity may see less harm from climate change than other livestock-producing regions.[127,128] Rising temperatures and elevated carbon dioxide levels are projected to increase growing-season length and carbon assimilation by plants, thus increasing aboveground net primary productivity (atmospheric carbon converted into aboveground plant matter)[129,130,131] but decreasing nutritional quality.[132,133] However, drought-induced water limitation would produce the opposite response by reducing biomass production, concentrating nutrients, and enhancing forage quality.[134] While the northern part of the region could see more frequent forage surpluses under both intermediate (RCP4.5) and very high (RCP8.5) scenarios, the southern part of the region (e.g., Nebraska) may experience more frequent forage deficits.[1] Drought years have had a smaller impact on cattle numbers in the Northern Great Plains than

in other regions,[135] and single-year droughts have only minimally impacted management or livelihoods.[136] However, ranchers face increasing challenges managing livestock health due to heat stress, parasites, and pathogens, as well as managing shifts in forage species, including invasive weeds.[137,138] Tribal producers may be more vulnerable to these stresses, as they tend to operate smaller farms and ranches on lands that have highly fractionated ownership, compared to non-Indigenous producers.[139] While cattle production has moved northward overall,[1] additional stressors to rangeland-based livelihoods exist in the region, including conversion to cropland,[140] rising land prices, and land ownership concentration trends.[141,142,143]

Geography of Land Use and Social Vulnerability



The Northern Great Plains region shows wide geographical variations in land use and social vulnerability.

Figure 25.8. The figure shows the geography of resource- and land-based livelihoods and vulnerabilities. Tribal reservation and trust lands are outlined on all maps. Panel (**a**) displays the predominant use of each county's agricultural land as either pasture or cropland. Pasture is common throughout much of the region, with cropland prev-

alent in the eastern portion of the region. Panel (**b**) shows federally owned public lands, including lands managed by the National Park Service, Bureau of Land Management, Bureau of Reclamation, US Forest Service, US Fish and Wildlife Service, Department of Defense, Department of Energy, and other federal agencies. In addition to public lands, private protected areas voluntarily provided to the database are also included but make up a very small minority of the overall public and other protected land area. The amount of federally owned public land increases in the more arid western portion of the region. Panel (**c**) displays locations of major energy sources in the region. Surface coal mines, oil and gas wells, and wind turbine installations are located throughout the region. Panel (**d**) shows county-level Social Vulnerability Index (SoVI) scores, with higher scores closer to 1 indicating higher levels of social vulnerability to environmental hazards.[144] Capital letters in panel (d) display locations of recent extreme climate events highlighted in the "Community Infrastructure and Quality of Life" section below (A, D, and E highlight examples of flood impacts, B highlights storm damage, and C provides an example of drought impacts). Figure credit: University of Nebraska, USDA Forest Service, NOAA NCEI, and CISESS NC.

Tourism and Recreation

The region's public and private lands provide tourism revenue, as well as benefits to residents' quality of life (Figure 25.8b).[145,146] Climate-related trends and extremes are expected to affect ecosystem services, wildlife, and tourism, with associated economic impacts.[147,148] Higher temperatures in the Yellowstone River in August 2016 are blamed for a fish kill that triggered the closure of the river to fishing and other uses, decreasing income for local and regional businesses.[149] Water-based activities are particularly vulnerable to drought and face increased conflicts with other water uses.[150] In 2017, Montana lost approximately 800,000 visitors and $289 million (in 2022 dollars) of tourism- and recreation- related income due to drought.[151] Visitors also shortened their stays due to smoke and fires.[150] Warmer winter temperatures in recent decades are correlated with mountain pine beetle outbreaks in western Montana but were not significantly correlated with mountain pine beetle outbreaks in other forests within the region, such as the Black Hills.[152] A 2017 drought decreased pheasant populations, affecting tourism income; its impact on wildlife populations also reduced Tribal-guided hunting opportunities and may have affected the competitiveness of culturally significant plants.[126] The length of winter sports seasons is expected to decrease[153] and thus negatively affect recreation economies in Montana, Wyoming, and South Dakota.[154] However, there may be improved opportunities for spring and autumn "shoulder season" recreation and both positive and negative effects on wildlife-based activities.[150]

Energy

Energy revenue in the region supports local services, infrastructure, and income that includes per capita payments for some Tribal members.[155] Energy revenue can also create risks in the region stemming from short-term revenue volatility and long-term dependence.[156] The region has an extensive number of oil and gas wells, numerous surface coal mines, and increasing wind turbine installations (Figure 25.8c). The region's share of employees working in fossil fuel extraction is four times greater (1.8% of all jobs) than in the Nation as a whole (0.4% of all jobs).[5] Energy-related livelihoods are affected by climate change due to changes in power generation, transmission, and consumption, as well as shifts in demands for particular types of energy sources.

Climate change impacts and mitigation efforts are expected to change energy demand in the Northern Great Plains seasonally. Higher summer temperatures and heatwaves are expected to increase energy demand in the Northern Great Plains and throughout the country, while in the region, higher winter temperatures and fewer cold snaps are expected to reduce energy demand for heating (Ch. 5).[157,158] Increased energy demands from outside the region will place increased demands on regional energy resources and electricity supply.[159] Lower winter electricity demands may potentially lower annual household energy costs in this region,[157] but increased electrification of the grid may increase costs to utility ratepayers as natural gas utilization declines.[160] Finally, climate change, especially climate extremes, may also stress energy infrastructure (e.g. rail, pipelines, distribution lines, transmission lines; Ch. 5).[161,162]

Energy-related livelihoods are also affected by shifts in the type of energy harvested. Energy extraction and generation in the region respond to external market and policy drivers.[163,164,165] For example, coal extraction has declined since 2011 due to air quality regulations, competition with lower-cost natural gas and renewables, and climate policy in states and utilities outside the region.[155] Tribal and other rural communities dependent on coal extraction for revenue and jobs have experienced losses to both as markets shift away from these resources.[166] Energy transition policy is heterogenous at the state level, and states in the region have pursued efforts to protect coal assets rather than help communities transition from coal.[155,167,168] In response to the demand for oil and gas, communities engaged in oil and natural gas extraction in the Northern Great Plains region grew faster than the regional average (14% compared to 6%),[8] and oil and natural gas extraction is expected to remain at or near current levels through 2030.[169] Renewable energy production is on the rise in the Northern Great Plains, with the region supplying 12% of the total US electricity generation from wind, biomass, and solar sources.[163,170] Wind electricity generation tripled in the region between 2011 and 2021 and was often co-located alongside row crop agriculture (Figure 25.8).[159,170] A growing number of Tribal entities are leading the Nation's renewable energy transition by installing renewable energy projects, including the Pine Ridge Indian Reservation in South Dakota (solar), the Oceti Sakowin Power Authority (wind), and the Confederated Salish and Kootenai Tribes in Montana (hydroelectric).[171,172,173] The Inflation Reduction Act of 2022 (IRA) is expected to accelerate deployment of renewable energy sources,[169] and the region may benefit from investments in hydrogen hubs; carbon capture, utilization, and storage; and advanced nuclear reactors (Ch. 5).[174] Without the IRA and other climate mitigation policies, additional energy produced by new renewable energy sources is expected to only meet the increased energy demand by 2050 rather than replace the current usage levels of petroleum and natural gas.[163]

Community Infrastructure and Quality of Life

Tribal lands, governments, and peoples are integral to the energy, agriculture, and recreation sectors. Immigrant populations are tied to agriculture in the region through their role in meatpacking, dairy, and other key industries. These communities face social vulnerability to harm from environmental hazards (Figure 25.8d). Communities across the region have experienced damages to infrastructure, businesses, homes, and livelihoods due to extreme events, including drought (2017, 2021), hailstorms (2018), flooding (2019, 2022), and wildfire (2021).[41] For example, after the 2019 Nebraska floods, community-level impacts included damage to homes, lack of water and sanitation services, and increased levels of anxiety and stress.[175] The effect of floods on the Santee Sioux Tribe included interruptions to power and drinking water supplies, wastewater backups, and destruction of many bridges and buildings (Figure 25.8d, point A).[176]

Future extreme events will disproportionately affect communities in the Northern Great Plains region that have greater exposure and sensitivity to hazards and fewer resources to prepare, respond, and adapt compared to larger cities.[12] For example, two storms damaged nearly 600 homes on the Pine Ridge Indian Reservation in July 2018, half of which were not repaired one year later (Figure 25.8d, point B). In 2019, the region experienced widespread flooding and damaged roads,[177] stranding many residents without access to basic needs. Many communities were disconnected from major highways, and infrastructure repairs are still underway. In drought years, communities dependent on surface water, such as those across the Crow Reservation, are seeing water resources and adaptation options become increasingly scarce (Figure 25.8d, point C).[166]

The lack of resilient infrastructure combined with regional climate impacts has created extreme water insecurity for Indigenous communities.[178] In the region, $159 million (in 2022 dollars) would be needed to bring either sewer or water access to 175 Tribal communities. Further, there are upwards of 18,000 homes within the region in need of sanitation (water and sewer) repair.[179]

Finally, regional residents living in housing or locations that are vulnerable face potential harms due to climate change. States in the region have a higher percentage of mobile and manufactured homes (e.g., 12.3% in Wyoming and 10.4% in Montana) compared to the US average (5.5%).[8] Mobile and manufactured homes are physically more vulnerable to extreme heat, flooding, and wildfires, exacerbating impacts from disasters.[180] Homes in floodplains are disproportionately occupied by renters and non-White populations. In Nebraska, Hispanic residents are overrepresented in floodplain areas (18% compared to 9% of residents in non-floodplain areas),[181] which resulted in disproportionate impacts to their housing security during the 2019 flooding in areas like Fremont and Grand Island, Nebraska (Figure 25.8d, points D and E).

Key Message 25.4

Climate Response Involves Navigating Complex Trade-Offs and Tensions

Climate change is creating new, and exacerbating existing, tensions and trade-offs between land use, water availability, ecosystem services, and other considerations in the region, leading to decisions that are expected to benefit some and set back others (*very high confidence*). Decision-makers are navigating a complicated landscape of shifting demographics, policy and regulatory tensions, and barriers to action (*high confidence*). Changes in temperature and precipitation averages, extremes, and seasonality will alter the productivity of working lands, resulting in land-use shifts to alternative crops or conversion to grasslands (*likely, medium confidence*). Shifts in energy demand, production, and policy will change land-use needs for energy infrastructure (*likely, medium confidence*).

Communities across the Northern Great Plains region experience complex tensions and trade-offs between land use, water availability, ecosystem services, and other factors, all exacerbated by the impacts of climate change. For example, higher temperatures and a longer growing season make the region attractive for climate-driven human migration[9] and increased forage production,[1] which in turn increase the demand for water resources. However, shifts in precipitation and reductions in snowpack will alter the quantity and timing of available water.[60] These tensions culminate in difficult decisions about how best to manage water quantity and quality and balance trade-offs between consumptive and ecological uses. Chapter 18 highlights frameworks for understanding complex systems, cascading effects, and decision-making under uncertainty.

Tensions: Navigating Barriers to Mitigation and Adaptation

Decision-makers are increasingly aware of current and projected climate change impacts, and communities are trying to adapt and mitigate. However, there are cultural, structural, and institutional barriers that prevent effective action in the Northern Great Plains region. States within the region currently rely on fossil fuel economies, creating resistance to energy transition and economic diversification.[155,156,182] For example, Wyoming has passed legislation designed to hamper the retirement of coal plants and to ensure a continued market for coal generation.[167] Other examples of barriers include less research funding than other regions;[183] lowered capacity to adapt (Box 25.1); varying perceptions of climate change;[184] and a confusing, and occasionally contradictory, set of water regulations and rights around surface water storage (e.g., implementation of artificial beaver dams to retain water on the landscape).[185,186] These factors limit transition planning and undermine community-level resilience.[168]

Integration of climate change into K–12 science education standards in the Northern Great Plains region varies greatly, with several states in the region failing to link human activities to climate change.[187] Acceptance of the human link to climate change is lower than the national average among adults in the

Northern Great Plains region, with particularly low acceptance among agricultural producers and agricultural interest groups.[188,189] This lack of acceptance highlights barriers to collective understanding and climate change response in the region and is matched by a stronger evidence base for actions that emphasize adaptation and resilience rather than mitigation (KM 25.5).

The employment, income, and public revenue impacts of the transition away from fossil fuels will vary by geography.[190,191] Declines in coal demand have, and will continue to have, negative effects on rural coal-dependent states and communities, such as Rosebud and Big Horn Counties in Montana.[155,156,192] The public revenue gains from renewable energy could be substantial but uneven, reflecting both the impact of facility siting on regional economic opportunity and the impacts of tax policy on the ability of state and local governments to capture and retain tax revenue.[155,193,194] Specifically, state taxation and expenditure limits preempt governments from generating revenue from diversified economic growth,[195] including from renewable energy, and tax incentives designed to lower costs for renewable energy projects can undermine the revenue benefits of an energy transition.[196] Tribal communities in this region also face barriers to developing and benefiting from renewable energy on Tribal lands, including a dependence on federal agencies for permitting, limited access to private finance, and an inability to access federal incentives, which makes private investment on Tribal lands less attractive.[197,198] Decision-makers and communities in the region have increased efforts to incorporate multiple values and ways of knowing (e.g., Indigenous Knowledge, local experience, and empirical science) into planning and action (KM 25.5).

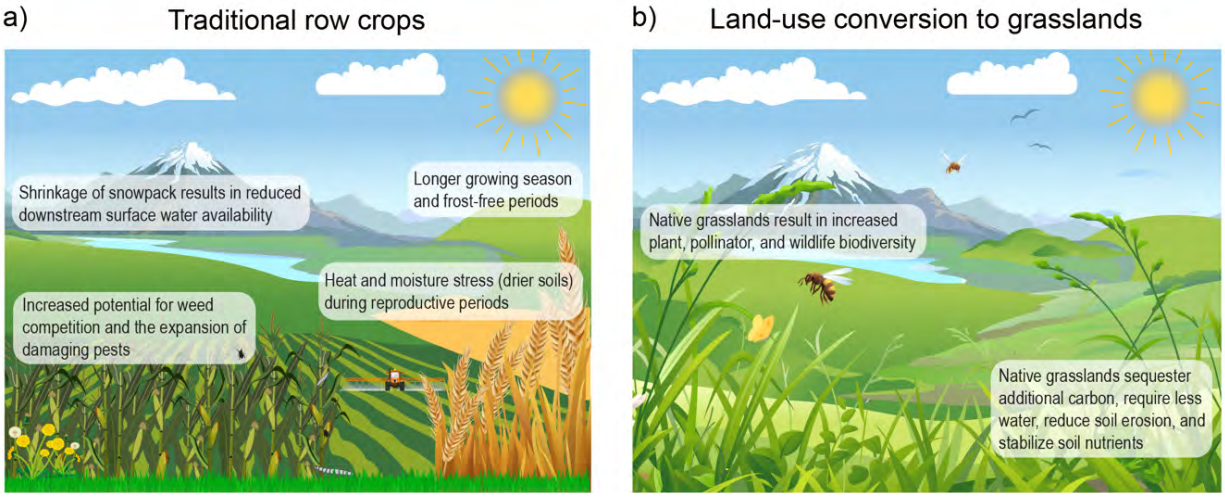
Box 25.1. Rural Capacity and Funding

With $1.28 trillion (in 2022 dollars) in funding, the Infrastructure Investment and Jobs Act is one of the largest investments in infrastructure, community resilience, and climate response in US history.[199] To successfully plan for and finance climate mitigation and adaptation projects, communities require capacity, staffing, resources, and expertise to apply for funding; fulfill reporting requirements; and design, build, and maintain infrastructure projects over the long term.[200] States where capacity to support these efforts is limited receive fewer federal resilience grants, and federal programs that create a need for capacity to apply for and manage grants can erode local capacity that could be utilized for other purposes, thereby discouraging participation.[201] Federal funding agencies can utilize maps of capacity at the local-government level to identify and support communities that lack staff and expertise to compete for climate mitigation and adaptation, community resilience, and economic development resources. Montana, Nebraska, North Dakota, and South Dakota rank among the 10 states where the greatest share of communities have a Rural Capacity Index lower than the national medium.[202] Key Message 20.3 further describes the role of governance and policy in risk, adaptation, and equity.

Trade-Offs: Land-Use Conversion

To counterbalance the potentially negative effects of a warmer future climate and drier soils, a shift to more water-conservative and nutrient-retentive land cover may be needed, such as from row crops to grassland (Figure 25.9). This would enhance ecosystem services such as wildlife, flood retention, nutrient stabilization, and carbon sequestration.[203,204] While this would increase resilience, it would also require many social and infrastructure adjustments and investments, including identifying seed sources for native species. Crops and services produced would shift from grain to forage, animal products, native plant seed, biofuel from grass, increased hunting on private land, and carbon credits. This would disadvantage companies that currently serve the high-input needs of conventional farmers but result in smaller loans for grassland producers due to less costly equipment, smaller seed purchases, and less grain shipped overseas.

Land-Use Conversion as a Strategy for Climate Adaptation



Land-use conversion offers one strategy for adapting to climate change.

Figure 25.9. Climate stressors interact with regional land-use decisions in complex ways. Recent and historical land-use decisions (**left**) are altering the productivity of working lands. Potential alternative land-use decisions (**right**) have the potential to increase resilience against climate change. By converting agriculture to grassland in areas that will become marginal for production, landowners and resource managers can conserve water and enhance ecosystem services. Figure credit: USGS.

Transitioning away from fossil fuel energy systems is expected to result in the abandonment or reduction of fossil fuel energy infrastructure (e.g., pump jacks, well bores), siting of new wind energy generation (e.g., wind turbines), construction of linear transmission CO_2 pipelines, and continued land conversion to biofuels.[165,205] Because renewable energy sources are expected to require larger land areas (3 to 25 times larger) to produce similar amounts of energy as nonrenewables,[206,207] a trade-off exists between providing energy and conserving the few remaining intact grassland tracts in the world.[208,209] Fragmentation of these tracts by energy infrastructure involved in harvesting and transmitting energy can reduce wildlife populations and provide conduits for invasive species.[159] Siting of energy infrastructure on areas already disturbed by row-crop agriculture or other activities may help prevent further fragmentation in some areas but may not be a possibility in the more intact grasslands of the Northern Great Plains that are relatively undisturbed.[159,209,210] Water-use trade-offs are another concern with energy development. Water law can influence the ability of industry to access water rights in low-flow years.[211] For instance, state and federal environmental policy may limit options to generate power from fossil fuel plants that require water for cooling during low-water years, which are projected to become more frequent (KM 25.1). Additionally, legal challenges related to water quantity and quality for endangered fish set up trade-offs between energy, wildlife, and recreation.[212,213]

Another adaptation action, piloted locally on less productive farmland with promising regional mitigation potential, is planting low-input, productive tall grasses, such as switchgrass, as dedicated biofuel energy crops (Figure 25.10).[214] This approach sequesters carbon from the atmosphere,[215,216] and marketing this alternative crop for forage, seed, or biofuels could generate income equal to or exceeding current income.[217] Switchgrass is a native plant that requires little fertilization and is especially resilient to drought. Biofuel feedstocks could be burned to generate electricity or converted to ethanol or bio-oil, syngas, and biochar. Planting grasses would store more carbon in the soil, require fewer inputs of fossil fuel compared to the annual planting of conventional crops, and improve other components of soil health.[218] However, large-scale land-use conversion to biofuel energy crops could disrupt food production processes, reduce biodiversity, and drive water competition.[219]

Marginal Farmland Planted to Switchgrass

Conversion of cropland to production of biofuels such as switchgrass is being piloted in the region as a climate adaptation action.

Figure 25.10. Switchgrass is a highly productive native prairie perennial that is the most promising species for future commercial growth as biofuel (for use as liquid transportation fuels and in electricity production). Photo was taken in 2021 at an experimental farm near South Shore, South Dakota, following two summers of drought, when production of switchgrass hay was 5 tons per acre and was more profitable than the production of corn. Key Message 25.5

Communities Are Building the Capacity to Adapt and Transform

Adaptation is underway in the Northern Great Plains to address the effects of climate change. Agricultural communities are shifting toward climate adaptation measures such as innovative soil practices, new drought-management tools, and water-use partnerships (*medium confidence*). Several Tribal Nations are leading efforts to incorporate Traditional Knowledge and governance into their adaptation plans (*high confidence*). Resource managers are increasingly relying on tools such as scenario planning to improve the adaptive capacity of natural ecosystems (*medium confidence*).

Effective adaptation accounts for climate change uncertainty as well as the complex interactions and trade-offs within and between ecological and social systems (Ch. 31).[220,221] The failure to carefully navigate the full suite of adaptation options and the consequences of those options can result in maladaptation—increased vulnerability to climate change due to poor or misguided action (Box 25.2)[222] or inequitable distribution of outcomes. Despite these challenges and risks, climate adaptation planning also presents opportunities to build collaborative partnerships and steward ecosystems.[223] The communities, economic sectors, and natural resource practitioners in this region are advancing adaptation solutions (Box 25.3).

Box 25.2. Prairie Pothole Wetlands and Climate Adaptation Challenges

In the eastern Prairie Pothole Region of Minnesota, North Dakota, South Dakota, and Iowa, an increase in rainfall in the spring season has exacerbated problems with excess shallow groundwater in farm fields. Farmers have responded by draining this water with perforated plastic pipes (known as tiles; Figure 25.11)[224,225] buried at the rooting depth of mature corn plants, a practice that improves crop yield.[226] Tiling has increased rapidly in eastern North and South Dakota, particularly in the Red River valley.[227,228,229,230] To date, approximately half of the wetlands in the Northern Great Plains have been drained, disrupting their ecosystem services, such as flood protection, carbon sequestration, and forage and water for livestock.[231,232] Drainage transforms the hydrology of downslope ecosystems, contributing to the widening and sedimentation of rivers,[224,233,234,235] and promotes toxic algal blooms in aquatic systems through transport of nutrients (especially phosphorus and nitrate).[236,237] Additionally, improper placement of tiles may drain water from nearby wetlands.[226] Adaptation actions to regain wetland benefits and respond to climate change include restoring grassland and drained wetlands, redoubling the protection of wetlands with easements, revising vegetation management of wetland watersheds, and discouraging tile drainage in farm fields with wetlands present.[238,239,240,241]

Pattern Field Tiling

Draining agricultural fields through tiling improves crop yields but can harm ecosystems.

Figure 25.11. Pattern field tiling in the Prairie Pothole Region is designed to drain low, wet ground to provide soil space for roots of crops, which can increase yields. Tiling can inadvertently drain wetlands if placed too close to or below the elevation of the wetland bottom. Plastic pipe is buried at each black line visible in the photograph. Photo credit: USFWS.

Box 25.3. Climate Adaptation Successes

Climate adaptation happening in the Northern Great Plains region includes farmers in Nebraska testing new methods to improve soil structure and hydrologic function, Indigenous communities returning buffalo to their lands, ranchers returning less productive farmland to grassland for forage production, and local communities responding to flooding and working to improve flood readiness.

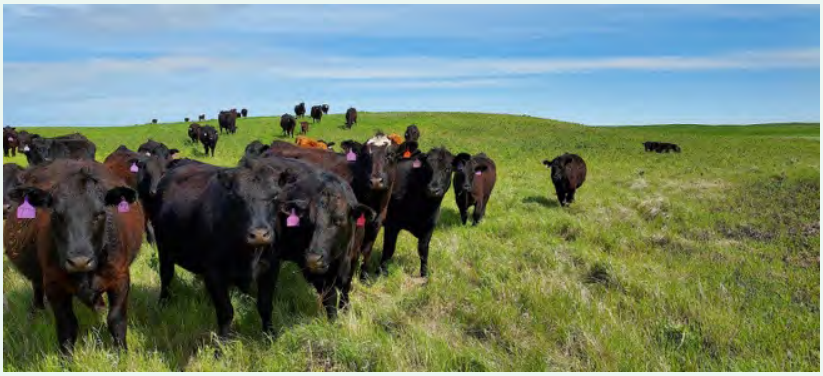
Adaptation Through Soil Health

Restoring soil structure and hydrologic function is a critical adaptation strategy in the Northern Great Plains region. In Nebraska, the Natural Resources Conservation Service has used federal conservation program dollars to support farmers testing soil health management practices, such as incorporating cover crops into annual crop rotations. Partnerships that leverage on-farm trials with outreach and research contribute to growing both the knowledge base and the execution of crop and livestock management practices that support improved soil function. Benefits include water-related outcomes such as increased infiltration and reduced runoff. Photo credit: USDA

Bringing Back the Buffalo

Bringing back the buffalo has been a regional resilience-building strategy for ranchers, Tribal Nations, and others who understand the role it plays in the ecosystem. The buffalo has deep cultural and spiritual significance for Tribal Nations in the region and beyond. The Tanka Fund has been pivotal in this regional effort by connecting ranchers to technical support and resources to increase herd sizes. Similarly, the InterTribal Buffalo Council helps Tribal Nations develop and maintain their own herds. These two entities connect resources to people and Tribal Nations looking to restore the buffalo as the keystone species of grassland ecosystems. Photo credit: NPS

Restoring Native Perennial Land Cover



As climate changes, it may be beneficial to return less productive cropland to native perennial cover that can provide multiple ecosystem services, including climate mitigation through carbon storage, pollinator benefits, and forage production for livestock. Audubon Great Plains, in partnership with government organizations and other nonprofits, is leading a new Conservation Forage Program in North Dakota to help producers achieve this shift in land use to benefit both producer operations and natural resources. Programs such as these that provide technical and financial assistance to producers while also helping to establish the necessary infrastructure for grazing (e.g., fencing, water access) and allow livestock use after vegetation establishment will allow farmers and ranchers flexibility in their operations. Photo credit: ©Reese Lausen

Responding to Increases in River Flooding

Flooding along major rivers is an increasing challenge for rural and Indigenous communities in this region. In March 2019, a 64-unit Tribal housing community with more than 300 Yankton Sioux members on the edge of the Lake Andes National Wildlife Refuge was inundated with floodwaters and cut off from the town of Lake Andes. Subsequent heavy rain events flooded basements and made the road inaccessible until the water over the highway froze in December. On August 12, 2019, the Tribe released a statement: "Our community is literally drowning."[242] The White Swan Recovery Group was created to provide resources for impacted community members and advocate for long-term solutions. The group received training to provide local lead and mold remediation and housing repairs. They continue to explore long-term solutions as the area is subject to frequent flooding; these efforts include advocacy to elevate the highway to protect housing, as well as conversations regarding relocating the community. Photo credit: Marcie Hebert, USFWS

Adaptations in Agriculture

The agricultural community in the Northern Great Plains region is developing innovative climate adaptation solutions to support livelihoods in the region (e.g., Johnson and Knight 2022[243]), many of which also support mitigation by sequestering carbon (Ch. 11). Stakeholders recognize that soil improvements increase flood and drought resilience.[244] Growing evidence from working farms and ranches in the region demonstrates how diversification strategies—such as reduced soil disturbance, increased crop residue, plant cover, and livestock and crop diversity (sometimes referred to as soil health or regenerative practices)—improve soil properties and processes, including water-holding capacity and infiltration, and provide many potential public and private co-benefits, including carbon sequestration.[245,246,247] These properties and processes produce enhanced carbon and nitrogen cycling and soil structure,[240] increased soil microbial communities, and lower pest communities while reducing nutrient inputs and leading to greater yields and profitability.[248,249,250,251,252] There is strong demand for, and proven efficacy around, producer knowledge networks to support transitioning to soil health practices.[253,254] Additionally, reintegrating row crop and livestock production systems could diversify income, increase operation resilience,[246] and restore ecosystem services, including sequestering more carbon in soil; retaining nutrients, especially nitrate; and supporting biodiversity.[108,217,255]

In arid parts of the region, adaptive solutions for irrigated agriculture will be critical. The majority of the region's states assign water rights based on prior appropriation, under which the first person to put water to beneficial use has the right to continue to use that water as long as the water is being used for the same beneficial use. This can slow the ability to acquire new water rights that may be necessary to address climate impacts.[256] The Upper Colorado River Commission (UCRC), as part of the 2019 Drought Contingency Plan,[25] is investigating the feasibility of implementing a demand-management program in the Upper Division states of the basin, including Wyoming. Under this program, water users would be compensated for voluntarily reducing consumptive uses. The conserved or imported water would be stored in federal reservoirs and released when needed to ensure compact compliance under a decision of the UCRC. On a smaller scale, many watershed and irrigation groups are investigating collaborative and shared water management strategies to manage scarce water resources to meet agricultural and ecological water needs, including the Brush Creek Irrigation District[257] and the Popo Agie Watershed Healthy Rivers Initiative[258] in Wyoming, as well as some Montana Tribes.[259] Instead of directly following the prior appropriation doctrines, different approaches to collaboratively manage water resources to meet agriculture and instream needs are being implemented. All of these efforts include and rely on improved hydrologic monitoring and data collection, as well as strong communication and buy-in from stakeholders.

Ranchers are also exploring adaptation strategies that increase livestock production by adjusting range management for a warmer climate.[260] One strategy to improve ranch resilience is through the use of drought planning.[261,262] Drought plans focus on identifying critical time periods for monitoring conditions and making decisions.[263] A planned drought response may involve adjusting the number of cattle, the season of grazing, the length of grazing time in pastures based on precipitation and vegetation growth,[264] or holistic planned grazing strategies that manage for ecosystem health by adapting to changing conditions.[265] A 2017 study found that nearly 60% of ranchers in the region had some type of drought contingency plan;[261] however, adoption of weather and climate data into management decisions has been slow.[136,266] The development of new grassland productivity forecasts may increase adoption by translating climate outlooks into usable information for ranchers.[267] Unique multistakeholder groups are also exploring collaborative adaptive management to understand and reconcile stakeholder experiences and ways of knowing about complex rangeland systems on public lands.[264]

Adaptation to Flooding

In response to significant flooding in 2011 and 2019 in the upper Missouri River basin (UMRB), improved monitoring was implemented to inform water management decisions. Frozen and saturated soil and significant snowpack in the UMRB were major contributors to flooding in those two years. Additionally, the drought west of the Missouri River in 2016–2017 highlighted the problem of sparse soil moisture data inhibiting accurate drought monitoring. As a result, the US Army Corps of Engineers, in collaboration with the state climate offices, is establishing a soil moisture and snowpack monitoring network.[268,269] A total of 529 stations are scheduled for installation between 2021 and 2027 on a 25-square-mile grid at elevations below 5,500 feet. The data from these stations, which include multiple soil moisture and temperature depths, as well as snow depths, will be directly available to NOAA to track and forecast flooding, drought, and other climatic and weather events.

With increased spring precipitation across much of the region, rural and Indigenous communities are adapting to more frequent flooding. Adaptation responses range from individual-scale approaches, such as elevating homes, to policy changes, including changing building codes and zoning regulations. Nebraska's unique river-basin Natural Resources District structure has enabled watershed-scale approaches that bring together multiple jurisdictions and stakeholders to decrease flood risk.[270] More drastic responses considered by some communities include relocating altogether. One increasingly successful adaptation strategy for responding to flood and natural disasters is the grassroots formation of local groups and coalitions to assist communities with disaster recovery and long-term adaptation (e.g., Sioux Empire Community Organizations Active in Disaster in South Dakota, Midwest Housing Resource Network in Nebraska). These groups are a mechanism for local communities to come together in mutual aid to plan for and support each other in response to flooding.

Adaptations in Indigenous Communities

Indigenous Peoples have called the Northern Great Plains region home for centuries, and today several regional Tribal Nations are leading the way in climate adaptation and implementation.[271,272,273] Several other Tribal Nations are leading the effort in water resilience and proactively addressing drought.[274,275,276,277] Indigenous approaches to adaptation combine traditional and contemporary management practices often grounded in spirituality and cultural traditions.[278] The key issues for Tribal climate adaptation in the region are capacity, sustainability, and sovereignty.[197]

The Rosebud Sioux Tribe has several initiatives in progress to build resilience to climate change.[279,280] The Sicangu Climate Crisis Working Group developed a Tribal climate adaptation plan that covers 20 Tribal communities across more than a million acres of Tribal land. The plan incorporates Lakota philosophy and Traditional Knowledge, including historical migrations, astronomy, origin stories, and the Tribes' special relationship with the buffalo. The plan prioritizes data sovereignty, interdepartmental collaboration, and directly supporting Tribal households to prepare for the impacts of climate change.[273] Additionally, the Rosebud Sioux Tribal Water Department has developed a drought adaptation plan and extensive real-time monitoring that enables the management of stream flow and groundwater sources, including the Ogallala Aquifer.[276] One of the major challenges has been the enforcement of the Rosebud water code to address neighboring farmers pumping Tribal-managed groundwater. However, with the removal of the moratorium on Tribal water codes, the Rosebud Sioux Tribe may now have the ability to manage its water as a sovereign nation.[281]

In 2018, the Blackfeet Nation completed a climate adaptation plan, which includes all of the natural resource departments across the Tribal government.[271] This inclusive approach takes more time and coordination but also creates collaborative opportunities by breaking down silos, minimizing redundancy, and maximizing scarce resources. For many Tribal Nations, sustainability is a key issue. This was especially true during

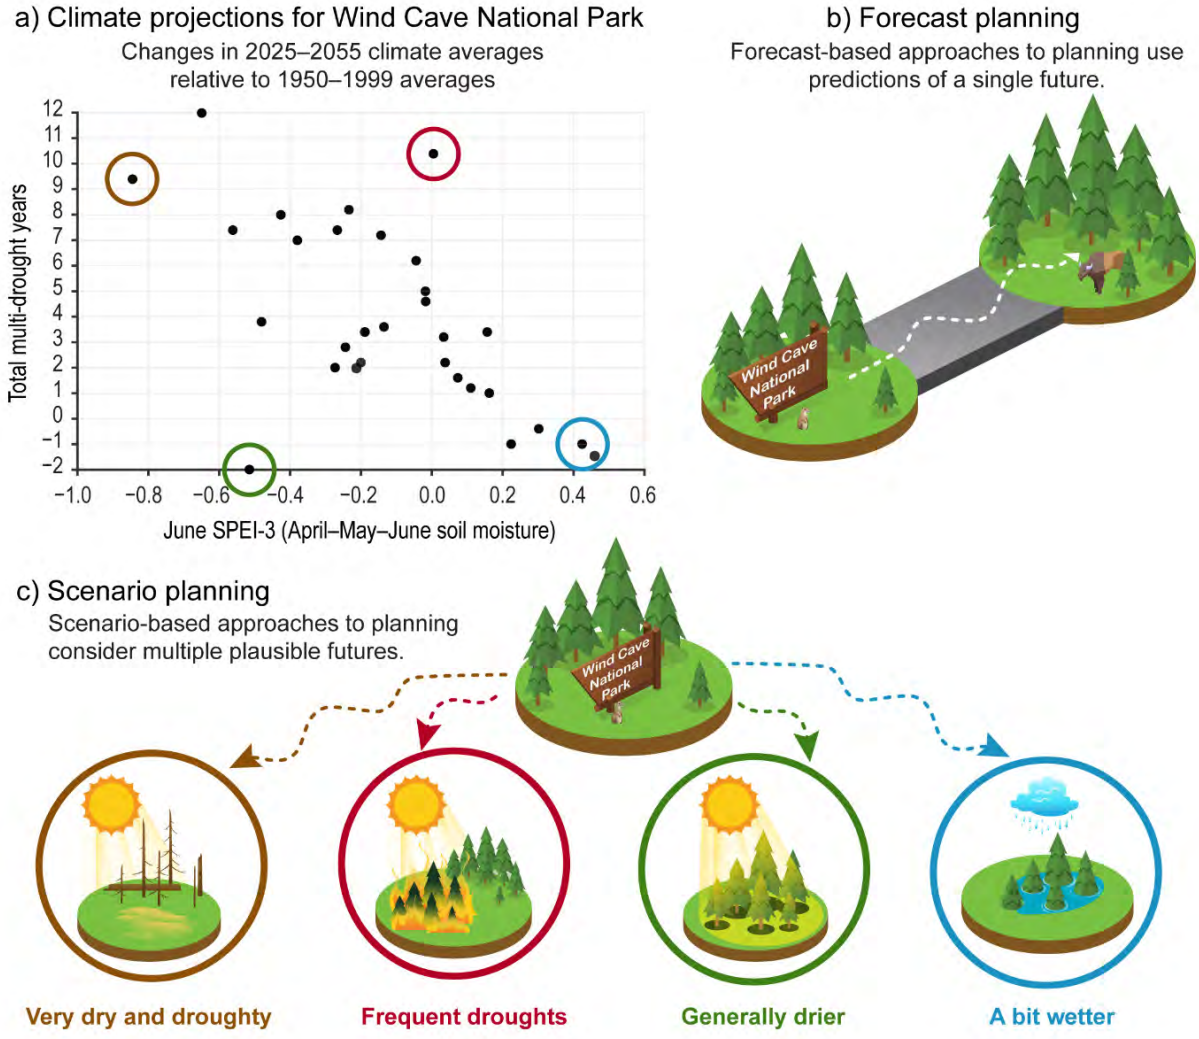
the COVID-19 pandemic and continues to be the reality in rural agricultural regions with smaller tax bases and higher turnover rates in staffing. Implementation includes the Ksik Stakii Project, which aims to protect beaver, restore rivers, and increase natural water storage to reduce vulnerability to drought and flooding.[271,282] A notable capacity-building strategy at Blackfeet is for Tribal resource departments to partner directly with Blackfeet Community College students on research projects. This type of a partnership is particularly important in the Northern Great Plains region, which has the highest concentration of Tribal colleges in the country.

Public Land Adaptation

The National Park Service (NPS) and partners have adapted scenario-based planning to help natural and cultural resource managers and others work with uncertainty and address the ways change might plausibly occur (Ch. 8).[283,284] Adaptation action on public lands in this region is challenged not only by the region's inherent climatic variability but also by the uncertainty in how resources, lifeways, or livelihoods might be affected by climate change and which adaptation responses might be effective (Figure 25.12).

Adaptation of scenario-based planning for public resource stewardship has focused on NPS units within the region—including Knife River Indian Villages National Historic Site, Badlands National Park, Wind Cave National Park, and Devils Tower National Monument.[283,285,286,287,288,289,290,291] This work has increased scenario plausibility and relevance and improved facilitation and efficiency of climate adaptation decision-making.[283] It has also clarified the importance of distinguishing climate futures (i.e., climate scenarios) from climate-resource scenarios (i.e., scenarios of both changes in climate and associated changes in resource condition).[289,292] Importantly, this work has created a model to support climate adaptation for natural resource decision-making in the face of climate uncertainty.

Adaptation Planning



Scenario-based planning accounts for uncertainty by considering a range of ways in which change might occur.

Figure 25.12. Forecast-based planning uses predictions of a single future (**b**), whereas scenario-based planning works with a set of plausible futures that capture a broad range of potential future conditions, providing a framework to support decisions under conditions that are uncertain and uncontrollable. Scenario-based planning at Wind Cave National Park identified four potential outcomes (**a**, **c**) for grassland and pine forest vegetation, surface water availability, and American bison (*Bison bison*) and prairie dog colonies under different climate futures—very dry and droughty (brown), frequent droughts (red), generally drier (green), and a bit wetter (blue)—all of which have different management implications for the natural and cultural resources in the park. Each dot in the graph represents a climate projection, and the set of four circled projections collectively encompasses most of the range of ways in which drought and springtime moisture levels could change by midcentury. SPEI—the Standardized Precipitation–Evaporation Index—is a multi-scalar drought index, based on precipitation and potential evapotranspiration, that is used to identify wet and dry periods in a given location.[293] A zero value indicates average moisture balance, positive values signify above-average wetness, and negative values represent drier-than-average conditions. SPEI-3 is a three-monthly SPEI calculation, and this figure shows values for April–June. Adapted from Schuurman et al. 2022[294] and Runyon et al. 2021.[289]

Rural Community Adaptation

Rural communities have two key needs to foster climate adaptation (KM 11.3). The first is economic diversification to create more resilient economies (e.g., broadband connectivity, restoration activities that create jobs and restore ecological function, and conservation that improves access and opportunity in recreation-based economies). The second is the need for a new social contract around resource extraction, especially for communities that will remain rural, isolated, and resource-dependent.[295] Major investments in community services, infrastructure, and economic development led by rural communities require long-term and sustainable funding to build capacity and resilience (Box 25.1).[194,200] Barriers to building adaptive capacity include a lack of coordinated federal assistance programs.[296] The region also has the potential for population growth in communities currently facing out-migration driven by favorable changes in climate coupled with a robust recreation economy, particularly in the intermountain West.[297,298]

Traceable Accounts

Process Description

The chapter lead authors were identified in the summer of 2021. This team compiled a list of nominated and Fourth National Climate Assessment (NCA4) authors as a pool of possible contributors. Additions to this list came from professional networks, research into priority departments at key regional institutions, and searches on several databases of experts from historically marginalized populations. The lead authors defined potential themes for the region based on team expertise and a review of literature published since the release of NCA4 and then narrowed the list of potential authors based on their ability to address these themes and a desire for diversity.

Candidates were selected based on a mix of expertise, regional distribution, career stage, age, gender, sector, discipline, and race and ethnicity. After preliminary research on potential contributors, introductory conversations were pursued to gauge interest and answer questions. The majority of the chapter team was recruited in September and October 2021, although as gaps were identified, other authors were added. Weekly all-author meetings started in September 2021 to craft the Zero Order Draft, with subgroup meetings held when needed to work out details. Once key topics were identified in December 2021, authors were divided into Key Message teams, based on interest and relevant knowledge. Virtual all-author meetings continued weekly, with Key Message teams meeting approximately every other week and more frequently before submitting the Zero Order Draft.

Key topics were identified through discussion, relevant literature, and knowledge of the region. Authors held two virtual engagement meetings, one during the day and one in the evening, to provide options for participants. Engagement events were promoted by the US Global Change Research Program through author networks, on social media, and with personal invitations to individuals whose voices the author team wanted to be represented. Feedback from engagement aligned well with the draft structure, but some of the emphases were adjusted based on stakeholder feedback. The author team incorporated inputs received in a public call for the technical material and relevant scientific publications and added several key technical contributors to bring other types of knowledge (e.g., Indigenous and experiential) that would provide a more complete assessment. Key Message teams discussed and came to consensus about Key Messages proposed in the First Order Draft and revised and came to consensus on Key Messages for the Second and Third Order Drafts. Key Messages were further iterated in the Fourth and Fifth Order Drafts to respond to comments from the public, National Academies, and agency technical review.

Key Message 25.1

Climate Change Is Compounding the Impacts of Extreme Events

Description of Evidence Base

The role of climate variability in the region has been well established.[39,42,299] The added effect of climate change is still emerging. NOAA State Climate Summaries document long-term increases in temperature in the region and varying changes in precipitation across the region.[14,15,16,17,18] Recent USGS trend and attribution efforts reflect the trends in flooding presented here, and the majority of attributions for those changes are related to changes in precipitation, with some also related to changes in temperature.[43]

The upper Missouri River basin combines the varying effects of east–west and north–south gradients in precipitation and temperature, respectively, for the Northern Great Plains. However, the Key Message team

wants to acknowledge that the Northern Great Plains region also includes parts of the Columbia, Colorado, Souris, Red, and Minnesota River basins.

Multiple independent scientific assessments and analyses of climate change effects on drought occurrence in the region are reaching similar conclusions across multiple climate change scenarios.[22,26,45,48,51] The study showing increased wildfire activity in the Northern Great Plains is based on satellite data, which adds credibility, because the use of the same methodology to assess wildfire across the region eliminates discrepancies caused by differences in how local governments record wildfire occurrence.[57]

Major Uncertainties and Research Gaps

Given the high degree of natural climate variability in the region, predicting future hydroclimatic and ecological conditions at specific locations is a major challenge. Climate change predictions of increased drought occurrence vary spatially and temporally. Complex interactions among temperature, precipitation, evapotranspiration, and moisture storage also create uncertainty for future conditions and agricultural production in this region (KM 3.4). As many of the projections of soil moisture predict close to no net change and the region already has a low effective precipitation that has high interannual variability, projected changes in soil moisture vacillate between overall net positive and negative changes.[47,48,49] Better understanding of how climate change affects soil moisture will require a greater assessment of the variability in soil moisture among global climate models and the incorporation of other factors such as soil type and plant species–specific responses at the local scale.[117,118]

Lack of long-term observations for small-scale and rare hail events and shortcomings in high-resolution models create uncertainty for predicting future events in specific areas,[28,29] so the models rely on trends in favorable hail environments.[30,31,32,33,34,35,300] Projections of severe convection in current research have largely focused on a very high scenario (RCP8.5).

Although drought frequency and severity are expected to increase, changes in multiyear drought occurrence due to climate change are relatively unknown.[45,52,53] Research on wildfires in the region has not addressed how human presence has influenced wildfire activity in the grasslands but has covered it in the forests.[58]

Description of Confidence and Likelihood

The coauthors of this section discussed the initial levels of confidence and likelihood, weighing the literature, observational data, and collective subject-matter expertise. The authors assigned a *likely* estimate with *high confidence* for an increase in severe droughts because of the pervasive evidence that increasing summer temperatures will increase evaporative demand, while changes in precipitation patterns lean toward increasingly dry summers. The authors assigned a *medium* confidence and no likelihood estimate for increasing hail frequency and size because the literature is still emergent and precludes a likelihood estimate but does present evidence that suggest increasing hail frequency and size in the High Plains area under at least some climate change scenarios. The authors assigned a *very likely* estimate with *high confidence* for changes in flood potential because research and observations strongly support both an increase of snowmelt runoff and flood potential in the eastern half of this region and respective decreases in the west. NOAA State Climate Summaries cited predict increases in extreme precipitation, which are expected to increase flood risk, even in areas with declines in overall precipitation. The authors assigned a *likely* estimate with *high confidence* for increased wildfire risk because the increase in evaporative demand and precipitation variability that favors drought also favors increased numbers of wildfires. Research indicating shorter duration of snowpack coverage also favors longer wildfire seasons. The authors assigned a *very likely* estimate with *very high confidence* for increases in evapotranspiration because multiple sources and subject-matter experts agree that the increasing warm-season temperatures will increase evaporative demand. The authors assigned a *very likely* estimate with *high confidence* for greater precipitation variability

because of the depth of both observational and model-based studies and consensus among subject-matter experts for current and future trends toward increased variability.

Key Message 25.2

Human and Ecological Health Face Rising Threats from Climate-Related Hazards

Description of Evidence Base

Climate trends from NOAA State Climate Summaries,[14,15,16,17,18] individual state-level climate assessments, USGS studies,[43] and demographic data from the 2020 US Census Bureau provided information to help characterize the region in terms of ecological conditions[99,100,101] and human populations.[61] CDC databases were also used extensively for health-related statistics. Multiple recent peer-reviewed studies of the impacts of specific aspects of climate change on human health were reviewed and included in the assessment. With relatively few region-specific studies of the health impacts of climate change, analyses based on areas with more concentrated populations provided valuable insights that are applicable to the Northern Great Plains. Several studies related to mental health have addressed the impacts on ranchers and farmers, rural residents, and Indigenous populations and are included in this assessment.[73,75,76] Many studies predict water quality changes in response to climate change; fewer studies have identified such changes.[90] Land-use change was predicted to be a larger driver of changes in water quality than climate change, and, along with management practices, land-use change appears to be the major driver in many cases;[90,91] however, the interaction of land use, management practices, and climate extremes is an important area for future research and potential harm reduction.[93,94,95]

Major Uncertainties and Research Gaps

The complex interactions among climate-related indicators themselves, with even more variability contributed by the considerable east–west geographical expanse of the region, lead to notable uncertainties for future climate conditions and the interactions between those climate conditions and local populations. The overall low population and population density across the region make data collection relative to health-related impacts difficult, adding to even more uncertainty in projections for impacts on individuals or locales. Research gaps include limited studies relating to health impacts specific to the region. In addition to the demographic barriers noted above, many areas within the region have limited sensors for measuring local conditions related to air quality, temperature, water quality, and air and soil moisture. The paucity of sensors, most notable in nonurban areas of the region, for these conditions introduces uncertainty when focusing on specific locations. The need for location-specific data is particularly important when addressing adaptive measures, since some conditions, such as air quality and temperature, can vary dramatically within small geographical areas.

Climate impacts on the ecology of the Northern Great Plains are difficult to generalize because individual species are expected to respond very differently to changes in climate. While declines have been observed and are projected for some taxa,[104,106] there are knowledge gaps around what those impacts might be for many taxa, species, and culturally significant plants and animals. Climate impacts will interact with and are expected to compound many other anthropogenic stressors, such as invasive species and conversion of natural ecosystems to row crop agriculture, and it is unknown which taxa are most vulnerable to climate change and what the magnitude of these impacts could be.

While the authors understand water-quality and physical processes related to climate, many management activities designed to reduce nutrients are taking place on the landscape, along with changing agricul-

tural nutrient requirements. Therefore, it can be difficult to find the climate signal in trends related to surface water quality, apart from the signal related to other important factors, such as land use, agricultural practices, and wastewater treatment.[90,94] The problem of attribution is further confounded by the complex effects of reaction-transport lags between any climate or landscape-scale driver and detectable changes in nutrients in surface or groundwater.[90,91] Recent findings based on observational data[90,91] support past predictions that land-use changes would have comparable or greater effects on water quality than climate changes.

Climate change has long been hypothesized as a driver of harmful algal blooms. Warming water temperature, higher carbon dioxide levels, and increases in heavy precipitation can create preferential conditions for algae. Blue-green algae can thrive in warming, slow-moving water; high carbon dioxide levels can result in rapid algae growth; and heavy precipitation can result in more nutrient runoff.[96] Unfortunately, supporting these hypotheses with observations has been challenging because of gaps in monitoring, lack of long-term algae data, and changes in laboratory and remote-sensing methods.[97,98]

Description of Confidence and Likelihood

Likelihood and confidence statements for climate change impacts on the health of residents of the region (*virtually certain*, *high confidence*) and on the region's ecology (*very likely*, *medium confidence*) are based on literature, some of which is cited in Key Message 25.2, observational data, and collective subject-matter expertise. The *very likely* rating for the region's ecology in both likelihood statements was based on the information that impacts are already being observed, and the *medium confidence* rating for both confidence statements was assigned because data or projections of impacts exist for some taxa but not all. Impacts to some aspects of the region's ecology are unclear or unknown. The research gaps and uncertainties listed in the preceding section limit the ability to project impacts for specific locations but do not lessen the confidence regarding current impacts on the various aspects of human health in the region as a whole, assertions strongly supported by an increasing number of studies (Ch. 15).[301] Levels of confidence and likelihood have been discussed in an ongoing fashion among the coauthors of the section, who weighed the overall literature and personal expertise to reach consensus for the stated levels.

Key Message 25.3

Resource- and Land-Based Livelihoods Are at Risk

Description of Evidence Base

Multiple national government economic reports provide the background for population growth and the importance of the agricultural and energy sectors to livelihoods in the Northern Great Plains. The most recent comprehensive syntheses of crop and climate impacts,[3,114,119] the most recent publications focused on Indigenous communities,[126] and the most recent foundational publications on crop physiology impacts of climate change at a broader scale than the region[120] support the projected negative impacts that rising temperatures would have on crop and culturally significant plant yields and timing. The net effect of climate change on agricultural livelihoods is uncertain due to the unresolved interacting effects of temperature, soil moisture, and carbon dioxide levels, as well as the degree of climate adaptations that may occur.[120,122] Projected aboveground net primary productivity increases and effects of drought are well documented across multiple scientific papers,[129,130,131] with recent papers supporting older papers from the literature and reinforcing the expected outcomes. The current resilience of rangeland-based livelihoods[135,136] and their future challenges[137,138] are well documented and in agreement. Although extensive peer-reviewed literature does not exist for climate effects on tourism and recreation, a few peer-reviewed literature examples documented climate change impacts on water-based, hunting, winter, and sightseeing recre-

ational activities.[150,151,153] The scientific literature on projected changes in electricity use within the region in response to climate change is readily available and in agreement (Ch. 5),[157,158] but literature on energy resource and electricity demands on the region from outside the region is limited and lacks specificity.[155,159] Examples of increasing and shifting types of energy demands on the region are well documented in both peer-reviewed scientific literature as well as government reports,[163,165,169,170] but comprehensive literature reviews providing overviews of how all energy shifts are occurring in relation to one another and in response to climate change and climate change policy are lacking. Literature on the effects of current and projected energy demand and shifts among types of energy sources on the livelihoods within the region is less available, and information is gleaned from government reports.[8] The impact of climate extremes on energy infrastructure is general in nature (Ch. 5)[161] and does not cover climatic variability and extremes unique to the region for all the energy infrastructure types found in the region.[162] Peer-reviewed literature on climate change impacts to livelihoods in the region does not fully address recent extreme events, so agency reports (e.g., FEMA 2019[177]) and Tribal documents (e.g., Blackfeet Nation 2022[139]) are used to document examples of impacts. This is also the case with Tribal infrastructure, where critical information on infrastructure was pulled from Indian Health Service and Bureau of Indian Affairs reports. Impacts are also identified by a technical contributor (Cullen) who works directly with communities affected by disasters in the region.

Major Uncertainties and Research Gaps

As stated in the text of the Key Message, the net effect of climate change on specific crop yields is uncertain, and multiple interacting effects would benefit from further study to fully grasp how climate change will comprehensively impact the agricultural industry, especially as it develops cultivars and management practices that adapt to the changing environment.

The net impact on forage quantity and quality in the region remains to be further explored. Productivity responses of Northern Great Plains rangelands to climate change have a degree of uncertainty, as the response of the vegetation to climate change may vary between the two dominant plant functional groups (C_3 and C_4). Scaling up the climate change responses of individual species and functional groups and how they contribute to larger ecosystem processes and properties, such as evapotranspiration or productivity, is important for improving the forecasting of climate change impacts to grasslands and shrublands in the region; this is a research gap. There is also uncertainty about how the negative impact of drought, which is expected to increase under climate change, will impact the expected positive gains on forage quantity and quality due to rising temperatures and elevated carbon dioxide.

Comprehensive studies of how climate change will affect tourism and recreation in the region are missing from the literature. Climate change impacts on tourism livelihoods are often limited to case studies and would benefit from more directed scientific study. Although some climate change models predict changes in insect outbreaks, which can lead to large impacts on recreational areas, correlations between outbreaks and climate change (e.g., mountain pine beetle) were not widespread, indicating a research gap in understanding all the interactions contributing to the relationship of observed outbreaks and climate change (e.g., Weed et al. 2015[152]).

Further studies detailing how increased national energy demand impacts regional energy harvest would provide a deeper understanding of the economic connections that in turn greatly affect regional communities. Strategic planning for the development of new oil and gas resources while transitioning to other energy resources in the region could benefit the grassland resource as a whole. Carbon capture, utilization, and storage (CCUS) in the region may play a role in mitigating US emissions. However, little carbon is currently being sequestered, and documentation of the costs and benefits for the region, as well as its many barriers and uncertainty, is a major research gap. It would be helpful to gather more information

on these topics before CCUS technology is deployed at scale in the region. Specific research examining how energy infrastructure in our region would respond to climate extremes is another research gap.

The effects of extreme events on agricultural, energy, and recreation-based livelihoods are often investigated more by the general media than by scientific studies and are therefore insufficiently covered in the research literature. This is also apparent when trying to evaluate the impact of climate change and climate extreme events on socially vulnerable communities. Peer-reviewed literature focused on climate change effects on rural and Indigenous communities in the region is a research gap.

Description of Confidence and Likelihood

The coauthors of this section discussed the initial levels of confidence and likelihood, weighing the literature, observational data, and collective subject-matter expertise. The authors assigned a *likely* estimate with *medium confidence* for agriculture and recreation seeing some positive but primarily negative effects of changing temperature and precipitation regimes on livelihoods. The *medium confidence* level was assigned because regional-specific agricultural literature is limited and requires multiple sources to be pieced together to evaluate the likelihood and confidence of changes in agriculture, and because recreation and tourism literature was limited to case studies often focused on extreme climate events that could increase with climate change. The authors assigned a *likely* estimate with *high confidence* to the statement that energy-sector livelihoods would be affected by shifts away from fossil fuel sources driven by emissions-reductions policies; this is because the coal industry has declined undeniably due to market competition, air-quality regulations, non-regulatory decisions made by public and private power utilities, and state and federal climate rules and renewable energy investments. Demand for oil and gas remains stable. The authors assigned a *likely* estimate and *medium confidence* to the statement that climate change will test the adaptive resilience of the region's socially vulnerable residents. This statement is assigned that particular likelihood and confidence because of instances in which recent extreme events have set back rural, Indigenous, and low-income communities, although there is a lack of extensive documentation or literature addressing this risk.

Key Message 25.4

Climate Response Involves Navigating Complex Trade-Offs and Tensions

Description of Evidence Base

The evidence that climate change is creating new and exacerbating existing tensions and trade-offs relies heavily on peer-reviewed literature cited throughout the chapter. There is increasing evidence and examples of how climate change is impacting, and will continue to impact, human communities and natural resources in the Northern Great Plains in complex and interacting ways.[167,219] The region is expected to see higher temperatures, a longer growing season, and shifts in water availability (KM 25.1) that will have impacts on livelihoods, land use, and water quantity and quality (KM 25.3). Climate change may also impact regional demographics over time, driving population growth of urban and amenity communities[9] and the continuing depopulation of rural communities.[5]

The evidence in the peer-reviewed literature indicates that when these impacts are combined, adaptation and mitigation decisions will result in benefits to some individuals and communities and have negative impacts for others. For example, as climate change alters the productivity of existing farmland, some producers are choosing to adapt by planting biofuel energy crops, such as switchgrass (Figure 25.10).[214] The peer-reviewed evidence identifies many benefits for such an action, including sequestration of carbon from the atmosphere,[215,216] sales that exceed current income,[217] and enhanced soil health and resilience

to drought.[218] However, peer-reviewed evidence also indicates that some communities may experience negative impacts, such as the disruption of food production processes, reduced biodiversity, and water competition.[219] Evidence for how decision-makers are navigating these trade-offs is emergent and highly dependent on local context.

Evidence has been well established in the peer-reviewed literature that individual and community knowledge and culture determines how climate change is experienced and managed (KM 20.2). Within this region, the acceptance of human-caused climate change is lower than the national average.[188,189] In a recent nationwide assessment,[187] several states in the region (Wyoming, Colorado, and North Dakota) had curricula that supported the notion that climate change is real and human-caused and can be mitigated, despite reliance on fossil fuel. Lower-scoring states (Montana and Nebraska) failed to link human activities to climate change or stated that climate change is controversial and that educating students about climate change should be the responsibility of parents (South Dakota). As a result of low acceptance and varied educational efforts, discourse in the region focuses on the adaptation and resilience effects of climate action rather than the mitigation effects (KM 25.5). These factors provide evidence of the complicated and shifting landscape for decision-making.

Peer-reviewed demographic and economic literature describes how the regional economy is reliant on agriculture and resource-based sectors (KM 25.3), so adaptation conversations have focused on land-use shifts to alternative crops (Figure 25.10),[214] conversion to grasslands (Figure 25.9),[203,204] and changes in energy infrastructure.[165,205] Many factors complicate the ability of communities in the region to adapt to climate change, but recent peer-reviewed data and literature highlight the high degree of rurality (Figure 25.1) and low capacity to compete for and utilize federal funds (Box 25.1) as particularly inhibiting.

Major Uncertainties and Research Gaps

Major uncertainties surround the choices that decision-makers and communities will make regarding the management and allocation of resources within the region and the impacts of those choices. There are additional gaps in understanding. For example, increased renewable energy in the region will impact labor opportunities in the region, but little is known on the labor effects of increased renewable energy. Estimates on land area that is required by different energy resources (e.g., wind versus oil) to produce similar amounts of energy are variable. Planning for minimizing grassland fragmentation while developing renewable resources with larger footprints could benefit from more accurate estimates.

Description of Confidence and Likelihood

Likelihood and confidence statements are based on literature cited in the narrative text, observational data, and collective subject-matter expertise. Confidence for the statement that climate change is leading to decisions that are expected to benefit some and set back others (*very high confidence*) was assigned based on the strong evidence of positive and negative effects of land-use change between agriculture, grassland, and energy in response to changes in climate (e.g., possible negative effects of large-scale conversion to biofuels).[219] Confidence for the statement that decision-makers are navigating a complicated landscape of shifting demographics, policy and regulatory tensions, and barriers to action (*high confidence*) was assigned based on the evidence of policy and decision-making around trade-offs in energy investment and infrastructure development (e.g., state legislation compelling, easing, or resisting energy transition),[167] although it's unclear how widespread such action is. Likelihood was not assigned to these two statements, as the uncertainty associated with human decision- and policymaking is difficult to quantify and is context dependent. For the statement that changes in temperature and precipitation averages, extremes, and seasonality will alter the productivity of working lands, resulting in land-use shifts to alternative crops or conversion to grasslands (*likely*, *medium confidence*), confidence and likelihood were assigned based on evidence of benefits from pilot actions in the region (Figure 25.10), although the scalability of these actions

to large geographies is still an area of study. For the statement that shifts in energy demand, production, and policy will change land-use needs for energy infrastructure (*likely*, *medium confidence*), confidence and likelihood were assigned based on evidence from the literature regarding the transition away from fossil fuel energy systems and its impact on abandonment of infrastructure[165,205] and possible fragmentation of existing grasslands due to new infrastructure.[159]

Key Message 25.5

Communities Are Building the Capacity to Adapt and Transform

Description of Evidence Base

Recent peer-reviewed literature provided the evidence base for adaptation actions being taken around soil health practices in the Northern Great Plains.[245,247] This literature has expanded significantly in recent years; the cited literature describes not only scientific understanding of soil changes and its related adaptive benefits but also research on farmer knowledge networks specific to this region. The evidence base for drought planning also draws from recent peer-reviewed literature and is growing.[261,262] The evidence base for diversification of grass-based livelihoods draws on a more limited peer-reviewed literature base and is more case specific.[217,246] Recent reports and planning efforts provide the evidence base for the newly implemented flood monitoring system in the upper Missouri River basin.[268,269] Reports, planning documents, limited peer-reviewed literature, and conversations with Tribal members provided the evidence for adaptation actions and challenges in rural and Indigenous communities.[271,272,273] A rapidly growing body of peer-reviewed literature provided the evidence for recent advances in ecosystem-based adaptation and scenario planning in the region (Ch. 8).[283,284]

Major Uncertainties and Research Gaps

Given the already high degree of climatic variability in the region and uncertainty in predicting future conditions, climate adaptation planning is a challenge. Despite these challenges, the evidence base shows that many climate adaptation actions are being tried across the region. In the process of implementing these adaptation actions, one of the major uncertainties is whether planned or implemented actions will ultimately be successful at helping communities or ecosystems adapt to climate change. There is a lack of research evaluating the success of climate adaptation actions, possibly due to insufficient time to judge success or a lack of robust monitoring and evaluation of outcomes. Furthermore, many climate adaptation actions are implemented in very context-dependent situations; therefore, it is uncertain how generalizable some adaptation actions or strategies may be.

Description of Confidence and Likelihood

It is difficult to quantify adaptation responses and to estimate their numerical variability. Therefore, the authors have not assigned any likelihood estimates to this Key Message. The authors assigned a *medium confidence* rating to the statement about adaptation actions in agricultural communities because there is evidence that a shift toward soil health and other adaptation practices is starting (e.g., Brown 2018;[245] Zilverberg et al. 2018[247]), but widespread adoption of these practices is not yet a reality. The authors assigned a *high confidence* rating to the third statement because there is good evidence that several Tribal Nations are leading efforts to incorporate Traditional Knowledge and governance into their adaptation plans (e.g., Blackfeet Nation 2018;[271] CSKT 2016;[272] Sicangu Climate Crisis Working Group 2022[273]). The statement about adaptation planning for natural resource managers is assigned a *medium confidence* rating because scenario planning is a well-developed tool and gaining traction in the National Park Service (e.g., Ch. 8),[283,284] but it is not yet being used widely outside of the National Park Service.

Introduction

Residents and visitors in the Southern Great Plains—Kansas, Oklahoma, and Texas—benefit from the region's working coasts, sandy beaches, southern forests, grasslands, urban areas, rural towns, scrublands, rangelands, and croplands. The region spans 20 ecoregions,[1] each with distinct and diverse species of plants and animals. Those ecosystems provide clean air and water, healthy soils, landscapes for recreation and tourism, habitats for wild plants and animals, and other benefits.[2] The region's 47 Federally Recognized Tribes were forcibly relocated to the region from elsewhere or constricted to fragments of their traditional homelands (circa 1830–1890).[3] Contemporary immigrants from many countries have joined generations of Indigenous Peoples and those who trace their roots to Mexico, Europe, and Africa.[4] The region's distinct peoples and ecosystems experience the impacts of climate change differently, requiring unique responses to climate risk and resources for resilience.

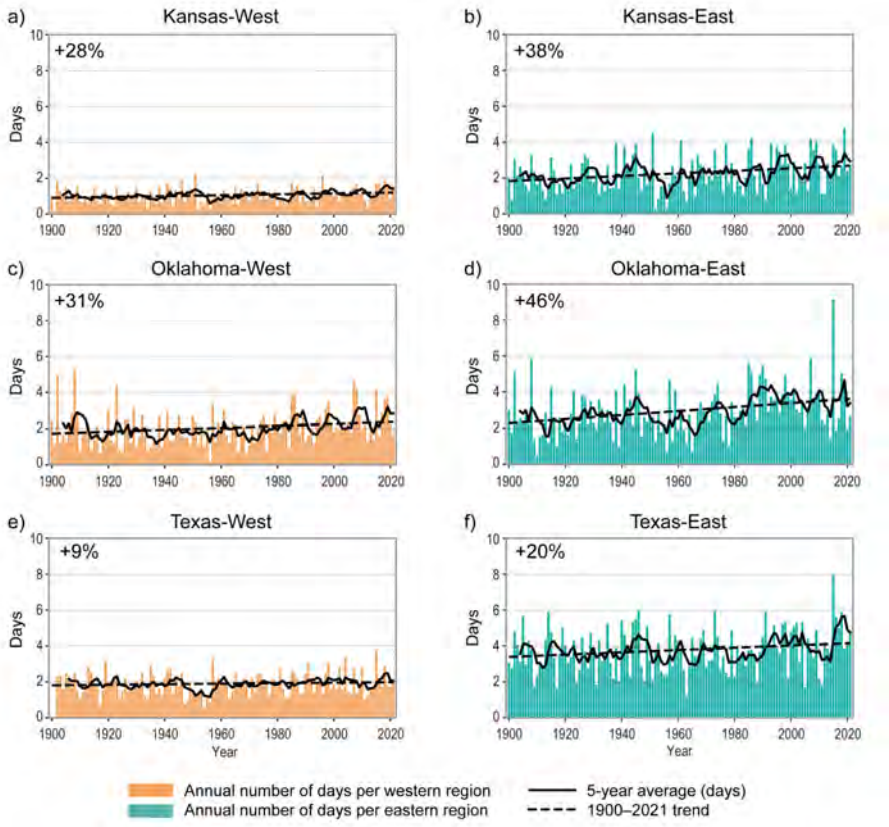
Water is unevenly available across the Southern Great Plains, contributing to distinct lifestyles, workforces, and social burdens. Annual precipitation amounts are lowest in the western portion of the region (10–15 inches) and increase substantially near the eastern boundary (over 50 inches), with high annual and seasonal precipitation variability everywhere.[4] Rivers generally flow from northwest to southeast, and shallow transient wetlands dot western landscapes. These surface waters are critical to sustain irrigation, livestock, and ecological diversity.[5,6] Groundwater is essential near and west of Interstate 35, with aquifers primarily supporting agricultural production and public water supply.[7] Although governments have created reservoirs for flood control, drinking water, irrigation, and recreation,[8] the region experiences some of the country's worst water shortages, and these are projected to increase in both intensity and duration.[9]

Energy is a dominant driver of the region's economy. The vast reserves of fossil fuels in the region have supported economic development nationwide and worldwide.[10] In the past two decades, wind and solar energy generation has proliferated across western lands. In 2021 Texas, Oklahoma, and Kansas ranked first (34,400 megawatts [MW] of installed capacity), third (10,400 MW), and fourth (8,300 MW), respectively, in the Nation in wind energy generation.[11] The reliability of renewable and nonrenewable energy generation and distribution is challenged by tropical storms, wildfire, heat, winter storms, flooding, and drought (KM 5.1).

The region encompasses some of the Nation's fastest-growing cities as well as many small rural communities with declining populations. Rural communities support much of the region's food, fiber, and energy production, in addition to recreational activities. The region's metropolitan areas are leaders in finance, research and development, service and energy industries, medical care, and tourism. Climate extremes and their impacts have harmed all communities, damaging infrastructure and agricultural production, disrupting commerce and price stability, and amplifying social inequities (KMs 11.1, 11.3, 12.2).

Although climate change is global (KM 3.1), its specific impacts are regional (KM 3.3). Thus far, the Southern Great Plains has seen fewer direct, large-scale impacts of climate change than other regions because of its relatively low latitude, flat terrain, and high natural climate variability. Even so, annual average temperatures have increased from 1900 to 2020: 1.5°F for Texas and Kansas[12,13] and 0.6°F for Oklahoma.[14] Annual precipitation has increased across most of the region except far west Texas (Figure 2.4). In addition, days with 2 or more inches of precipitation have become more frequent across the Southern Great Plains, with larger increases in the eastern half of the region than the western half (Figure 26.1).[15] Between 2000 and 2021, Texas endured its five wettest months on record, as well as 19 named tropical storms;[13] 8 of these storms were hurricanes, including Harvey (2017), Ike (2008), and Rita (2005). In contrast, over one-quarter of Kansas experienced severe to exceptional drought during 56 of the 156 months from 2010 to 2022. During this period, Oklahoma and Texas experienced 69 and 82 months, respectively, of these severe to exceptional drought conditions.[16] Between 2018 and 2022 NOAA reported 52 individual billion-dollar climate-related disasters affecting all or part of the region.[17]

Annual Number of Days with Precipitation of 2 Inches or More (1900–2021)



The frequency of days with precipitation of 2 inches or more has increased across the Southern Great Plains.

Figure 26.1. These graphs show the annual number of days (colored bars) with daily precipitation of 2 inches or more from 1900 to 2021 in (**a**) western Kansas (28% increase for the long-term, linear trend), (**b**) eastern Kansas (38% increase), (**c**) western Oklahoma (31% increase), (**d**) eastern Oklahoma (46% increase), (**e**) western Texas (9% increase), and (**f**) eastern Texas (20% increase). (Station data were unavailable for 1900 and 1901 in western Texas.) Solid black lines show five-year averages; dashed black lines denote the 1900–2021 trend. The number of days has been highly variable from year to year, with fewer 2-inch events in the west (gold bars) on average than in the east (green bars; divided at 97.5° west, near Wichita, Oklahoma City, Fort Worth, and Corpus Christi). Days with precipitation of 2 inches or more have increased in all six regions. Figure credit: NOAA NCEI and CISESS NC.
